The difficulty in expressing the cost of the security measures in monetary terms is one of the fundamental factors that make the communication between technical and administrative personnel difficult. An immediate consequence of this is the difficulty in securing the continuous commitment of higher management to supporting the security enhancement effort. This becomes even more difficult when organizational and procedural security measures are proposed. Both management and users are concerned about the impact of these measures in their usual practice, particularly when the widely accepted concept that security is purely a technical issue is put into doubt.

Moreover, protecting an information system calls for an integrated, holistic study that will answer questions such as: Which elements of the information system do we want to protect? Which, among these, are the most important ones? What threats is the information system facing? What are its vulnerabilities? What security measures must be put in place? Answering these questions gives a good picture of the current state of the information system with regard to its security. As research[1] has shown, developing techniques and measures for security is not enough, since the most vulnerable point in any information system is the human user, operator, designer, or other human. Therefore, the development and operation of secure information systems must equally consider and take account of both technical and human factors. At the same time, the threats that an information system faces are characterized by variety, diversity, complexity, and continuous variation. As the technological and societal environment continuously evolves, threats change and evolve, too. Furthermore, both information systems and threats against them are dynamic; hence the need for continuous monitoring and managing of the information system security plan.

The most widely used methodology that aims at dealing with these issues is the information systems risk management methodology. This methodology adopts the

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00058-1

concept of risk that originates in financial management, and substitutes the unachievable and immeasurable goal of fully securing the information system with the achievable and measurable goal of reducing the risk that the information system faces to within acceptable limits.

1. THE CONCEPT OF RISK

The concept of risk originated in the 17th century with the mathematics associated with gambling. At that time, risk referred to a combination of probability and magnitude of potential gains and losses. During the 18th century, risk, seen as a neutral concept, still considered both gains and losses and was employed in the marine insurance business. In the 19th century, risk emerged in the study of economics. The concept of risk, then, seen more negatively, caused entrepreneurs to call for special incentives to take the risk involved in investment. By the 20th century a total negative connotation was made when referring to outcomes of risk in engineering and science, with particular reference to the hazards posed by modern technological developments.[2,3]

Within the field of IT security, the risk R is calculated as the product of P, the probability of an exposure occurring a given number of times per year times C, the cost or loss attributed to such an exposure, that is, $R = P \; x \; C$.[4]

The most recent standardized definition of risk comes from the International Organization for Standardization (ISO),[5] where the risk is defined as "the effect of uncertainty on objectives". This definition, quite different from the definition in the past (2008) version of the same standard, is the result of the process of aligning definitions within the ISO 27000 series of standards with those within the ISO 31000 series. Notwithstanding the fact that this alignment facilitates the treatment of risk regardless of its kind (IT security, environmental, etc.) within an enterprise, it does not directly convey the true meaning of risk within the IT security context. Within this context, it makes much more sense to retain the older standardized definition of risk as "the potential that a given threat will exploit vulnerabilities of an asset or group of assets and thereby cause harm to the organization."

To complete this definition, definitions of the terms *threat, vulnerability*, and *asset* are in order. These are as follows: A threat is "a potential cause of an incident, that may result in harm to system or organization." A vulnerability is "a weakness of an asset or group of assets that can be exploited by one or more threats." An asset is "anything that has value to the organization, its business operations and their continuity, including information resources that support the organization's mission."[6] Additionally, harm results in impact, which is "an adverse change to the level of business objectives achieved."[7] The relationships among these basic concepts are pictorially depicted in Figure 53.1.

2. EXPRESSING AND MEASURING RISK

Information security risk "is measured in terms of a combination of the likelihood of an event and its consequence."[8] Because we are interested in events related to information security, we define an information security event as "an identified occurrence of a system, service or network state indicating a possible breach of information security policy or failure of safeguards, or a previously unknown situation that may be security relevant."[9] Additionally, an information security incident is "indicated by a single or a series of unwanted information security events that have a significant probability of compromising business operations and threatening information security."[10] These definitions actually invert the investment assessment model, where an investment is considered worth making when its cost is less than the product of the expected profit times the likelihood of the profit occurring. In our case, the risk R is defined as the product of the likelihood L of a security incident occurring times the impact I that will be incurred to the organization due to the incident, that is, $R = L \; x \; I$.[11]

To measure risk, we adopt the fundamental principles and the scientific background of statistics and probability theory, particularly of the area known as Bayesian statistics, after the mathematician Thomas Bayes (1702−1761), who formalized the namesake theorem.

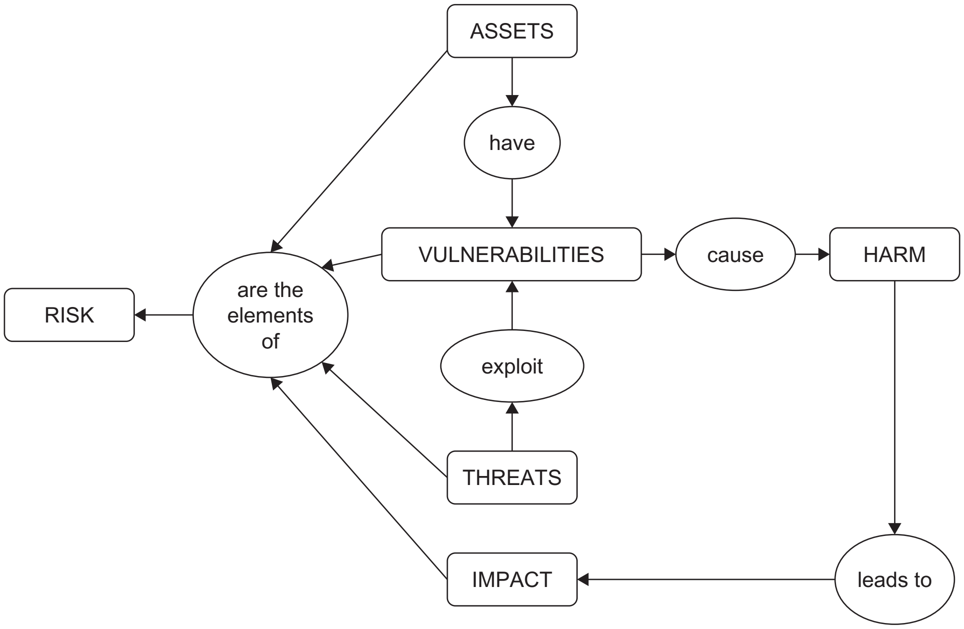

FIGURE 53.1 Risk and its related concepts.

Bayesian statistics is based on the view that the likelihood of an event happening in the future is measurable. This likelihood can be calculated if the factors affecting it are analyzed. For example, we are able to compute the probability of our data to be stolen as a function of the probability an intruder will attempt to intrude into our system and of the probability that he will succeed. In risk analysis terms, the former probability corresponds to the likelihood of the threat occurring and the latter corresponds to the likelihood of the vulnerability being successfully exploited. Thus, risk analysis assesses the likelihood that a security incident will happen by analyzing and assessing the factors that are related to its occurrence, namely the threats and the vulnerabilities. Subsequently, it combines this likelihood with the impact resulting from the incident occurring to calculate the system risk. Risk analysis is a necessary prerequisite for subsequently treating risk. Risk treatment pertains to controlling the risk so that it remains within acceptable levels. Risk can be reduced by applying security measures; it can be shared, by outsourcing or by insuring; it can be avoided; or it can be accepted, in the sense that the organization accepts the likely impact of a security incident.

The likelihood of a security incident occurring is a function of the likelihood that a threat appears and of the likelihood that the threat can successfully exploit the relevant system vulnerabilities. The consequences of the occurrence of a security incident are a function of the likely impact that the incident will have to the organization as a result of the harm that the organization assets will sustain. Harm, in turn, is a function of the value of the assets to the organization. Thus, the risk R is a function of four elements: (a) V, the value of the assets; (b) T, the severity and likelihood of appearance of the threats; (c) V, the nature and the extent of the vulnerabilities and the likelihood that a threat can successfully exploit them; and (d) I, the likely impact of the harm should the threat succeed, that is, $R = f(A, T, V, I)$.

If the impact is expressed in monetary terms, the likelihood being dimensionless, then risk can be also expressed in monetary terms. This approach has the advantage of making the risk directly comparable to the cost of acquiring and installing security measures. Since security is often one of several competing alternatives for capital investment, the existence of a cost/benefit analysis that would offer proof that security will produce benefits that equal or exceed its cost is of great interest to the management of the organization. Of even more interest to management is the analysis of the investment opportunity costs, that is, its comparison to other capital investment options.[12] However, expressing risk in monetary terms is not always possible or desirable, since harm to some kinds of assets (human life) cannot (and should not) be assessed in monetary terms. This is why risk is usually expressed in nonmonetary terms, on a simple dimensionless scale.

Assets in an organization are usually quite diverse. Because of this diversity, it is likely that some assets that have a known monetary value (hardware) can be valued in the local currency, whereas others of a more qualitative nature (data or information) may be assigned a numerical

12. R. Baskerville, "Risk analysis as a source of professional knowledge," *Computers & Security*, Vol. 10, pp. 749–764, 1991.

value based on the organization's perception of their value. This value is assessed in terms of the assets' importance to the organization or their potential value in different business opportunities. The legal and business requirements are also taken into account, as are the impacts to the asset itself and to the related business interests resulting from a loss of one or more of the information security attributes (confidentiality, integrity, availability). One way to express asset values is to use the business impacts that unwanted incidents, such as disclosure, modification, nonavailability, and/or destruction, would have to the asset and the related business interests that would be directly or indirectly damaged. An information security incident can impact more than one asset or only a part of an asset. Impact is related to the degree of success of the incident. Impact is considered as having either an immediate (operational) effect or a future (business) effect that includes financial and market consequences. Immediate (operational) impact is either direct or indirect.

Direct impact may result because of the financial replacement value of lost (part of) asset or the cost of acquisition, configuration and installation of the new asset or backup, or the cost of suspended operations due to the incident until the service provided by the asset(s) is restored. Indirect impact may result because financial resources needed to replace or repair an asset would have been used elsewhere (opportunity cost) or from the cost of interrupted operations or due to potential misuse of information obtained through a security breach or because of violation of statutory or regulatory obligations or of ethical codes of conduct.[13]

These considerations should be reflected in the asset values. This is why asset valuation (particularly of intangible assets) is usually done through impact assessment. Thus, impact valuation is not performed separately but is rather embedded within the asset valuation process.

The responsibility for identifying a suitable asset valuation scale lies with the organization. Usually, a three-value scale (low, medium, and high) or a five-value scale (negligible, low, medium, high, and very high) is used.[14]

Threats can be classified as deliberate or accidental. The likelihood of deliberate threats depends on the motivation, knowledge, capacity, and resources available to possible attackers and the attractiveness of assets to sophisticated attacks. On the other hand, the likelihood of accidental threats can be estimated using statistics and experience. The likelihood of these threats might also be related to the organization's proximity to sources of danger, such as major roads or rail routes, and factories dealing with dangerous material such as chemical materials or oil. Also the organization's geographical location will affect the possibility of extreme weather conditions. The likelihood of human errors (one of the most common accidental threats) and equipment malfunction should also be estimated.[15] As already noted, the responsibility for identifying a suitable threat valuation scale lies with the organization. What is important here is that the interpretation of the levels is consistent throughout the organization and clearly conveys the differences between the levels to those responsible for providing input to the threat valuation process. For example, if a three-value scale is used, the value *low* can be interpreted to mean that it is not likely that the threat will occur, there are no incidents, statistics, or motives that indicate that this is likely to happen. The value *medium* can be interpreted to mean that it is possible that the threat will occur, there have been incidents in the past or statistics or other information that indicate that this or similar threats have occurred sometime before, or there is an indication that there might be some reasons for an attacker to carry out such action. Finally, the value *high* can be interpreted to mean that the threat is expected to occur, there are incidents, statistics, or other information that indicate that the threat is likely to occur, or there might be strong reasons or motives for an attacker to carry out such action.[16]

Vulnerabilities can be related to the physical environment of the system, to the personnel, management, and administration procedures and security measures within the organization, to the business operations and service delivery or to the hardware, software, or communications equipment and facilities. Vulnerabilities are reduced by installed security measures. The nature and extent as well as the likelihood of a threat successfully exploiting the three former classes of vulnerabilities can be estimated based on information on past incidents, on new developments and trends, and on experience. The nature and extent as well as the likelihood of a threat successfully exploiting the latter class, often termed technical vulnerabilities, can be estimated using automated vulnerability-scanning tools, security testing and evaluation, penetration testing, or code review.[17] As in the case of threats, the responsibility for identifying a suitable vulnerability valuation scale lies with the organization. If a three-value scale is used, the value *low* can be interpreted to mean that the vulnerability is hard to exploit and the protection in place is good. The value *medium* can be interpreted to

An Agenda for Action for the Risk Management Framework

A risk-based approach to security control selection and specification considers effectiveness, efficiency, and constraints due to applicable laws, directives, executive orders, policies, standards, or regulations. The following activities related to managing organizational risk (also known as the Risk Management Framework) are paramount to an effective information security program and can be applied to both new and legacy information systems within the context of the system development life cycle and the enterprise architecture (Check All Tasks Completed):

_____**1.** Categorize the information system and the information processed, stored, and transmitted by that system based on an impact analysis.

_____**2.** Select an initial set of baseline security controls for the information system based on the security categorization; tailoring and supplementing the security control baseline as needed based on organization assessment of risk and local conditions.

_____**3.** Implement the security controls and document how the controls are deployed within the information system and environment of operation.

_____**4.** Assess the security controls using appropriate procedures to determine the extent to which the controls are implemented correctly, operating as intended, and producing the desired outcome with respect to meeting the security requirements for the system.

_____**5.** Authorize information system operation based upon a determination of the risk to organizational operations and assets, individuals, other organizations and the Nation resulting from the operation of the information system and the decision that this risk is acceptable.

_____**6.** Monitor and assess selected security controls in the information system on an ongoing basis including assessing security control effectiveness, documenting changes to the system or environment of operation, conducting security impact analyses of the associated changes, and reporting the security state of the system to appropriate organizational officials.

mean that the vulnerability might be exploited, but some protection is in place. The value *high* can be interpreted to mean that it is easy to exploit the vulnerability and there is little or no protection in place.[18]

3. THE RISK MANAGEMENT METHODOLOGY

The term *methodology* means an organized set of principles and rules that drives action in a particular field of knowledge. A *method* is a systematic and orderly procedure or process for attaining some objective. A *tool* is any instrument or apparatus that is necessary to the performance of some task. Thus, methodology is the study or description of methods.[19] A methodology is instantiated and materializes by a set of methods, techniques, and tools. A methodology does not describe specific methods; nevertheless, it does specify several processes that need to be followed. These processes constitute a generic framework (see checklist, "An Agenda For Action For The Risk Management Framework"). They may be broken down into sub-processes, they may be combined, or their sequence may change. However, every risk management exercise must carry out these processes in some form or another.

18. British Standards Institute, "ISMSs—Part 3: Guidelines for information security risk management," BS 7799-3:2006.

19. R. Baskerville, "Risk analysis as a source of professional knowledge," *Computers & Security*, Vol. 10, pp. 749-764, 1991.

Risk management consists of six processes, namely context establishment, risk assessment, risk treatment, risk acceptance, risk communication and consultation, and risk monitoring and review.[20] This is more or less in line with the approach where four processes are identified as the constituents of risk management, namely, putting information security risks in the organizational context, risk assessment, risk treatment, and management decision-making and ongoing risk management activities.[21] Alternatively, risk management is seen to comprise three processes, namely risk assessment, risk mitigation, and evaluation and assessment.[22] Table 53.1 depicts the relationships among these processes.[23,24]

Context Establishment

The context establishment process receives as input all relevant information about the organization. Establishing the context for information security risk management determines the purpose of the process. It involves setting

the basic criteria to be used in the process, defining the scope and boundaries of the process, and establishing an appropriate organization operating the process. The output of context establishment process is the specification of these parameters.

The purpose may be to support an information security management system (ISMS); to comply with legal requirements and to provide evidence of due diligence; to prepare for a business continuity plan; to prepare for an incident reporting plan; or to describe the information security requirements for a product, a service, or a mechanism. Combinations of these purposes are also possible.

The basic criteria include risk evaluation criteria, impact criteria, and risk acceptance criteria. When setting risk evaluation criteria the organization should consider the strategic value of the business information process; the criticality of the information assets involved; legal and regulatory requirements and contractual obligations; operational and business importance of the attributes of information security; and stakeholders expectations and perceptions, and negative consequences for goodwill and reputation. The impact criteria specify the degree of damage or costs to the organization caused by an information security event. Developing impact criteria involves considering the level of classification of the impacted information asset; breaches of information security; impaired operations; loss of business and financial value; disruption of plans and deadlines; damage of reputation; and breaches of legal, regulatory or contractual requirements. The risk acceptance criteria depend on the organization's policies, goals, objectives and the interest of its stakeholders. When developing risk acceptance criteria the organization should consider business criteria; legal and regulatory aspects; operations; technology; finance; and social and humanitarian factors.[25]

The scope of the process needs to be defined to ensure that all relevant assets are taken into account in the subsequent risk assessment. Any exclusion from the scope needs to be justified. Additionally, the boundaries need to be identified to address those risks that might arise through these boundaries. When defining the scope and boundaries, the organization needs to consider its strategic business objectives, strategies, and policies; its business processes; its functions and structure; applicable legal, regulatory, and contractual requirements; its information security policy; its overall approach to risk management; its information assets; its locations and their geographical characteristics; constraints that affect it; expectations of its stakeholders; its socio-cultural environment; and its information exchange with its environment. This involves studying the organization (its main purpose, its business; its mission; its values; its structure; its organizational chart; and its strategy). It also involves identifying its constraints. These may be of a political, cultural, or strategic nature; they may be territorial, organizational, structural, functional, personnel, budgetary, technical, or environmental constraints; or they could be constraints arising from preexisting processes. Finally, it entails identifying legislation, regulations, and contracts.[26]

Setting up and maintaining the organization for information security risk management fulfills part of the requirement to determine and provide the resources needed to establish, implement, operate, monitor, review, maintain, and improve an ISMS.[27] The organization to be developed will bear responsibility for the development of the information security risk management process suitable for the organization; for the identification and analysis of the stakeholders; for the definition of roles and responsibilities of all parties, both external and internal to the organization; for the establishment of the required relationships between the organization and stakeholders, interfaces to the organization's high-level risk

27. ISO/IEC, "Information security management—specification with guidance for use," ISO 27001.

management functions, as well as interfaces to other relevant projects or activities; for the definition of decision escalation paths; and for the specification of records to be kept. Key roles in this organization are the senior management; the chief information officer (CIO); the system and information owners; the business and functional managers; the information systems security officers (ISSO); the IT security practitioners; and the security awareness trainers (security/subject matter professionals).[28] Additional roles that can be explicitly defined are those of the *risk assessor* and of the *security risk manager*.[29]

Risk Assessment

This process comprises three subprocesses, namely risk identification, risk analysis and risk evaluation. The process receives as input the output of the context establishment process. It identifies, quantifies or qualitatively describes risks and prioritizes them against the risk evaluation criteria established within the course of the context establishment process and according to objectives relevant to the organization. It is often conducted in more than one iterations, the first being a high-level assessment aiming at identifying potentially high risks that warrant further assessment, whereas the second and possibly subsequent iterations entail further in-depth examination of potentially high risks revealed in the first iteration. The output of the process is a list of assessed risks prioritized according to risk evaluation criteria.[30]

Risk identification seeks to determine what could happen to cause a potential loss and to gain insight into how, where, and why the loss might happen. It involves a number of steps, namely identification of assets; identification of threats; identification of existing security measures; identification of vulnerabilities; and identification of consequences. Input to the subprocess is the scope and boundaries for the risk assessment to be conducted, an asset inventory, information on possible threats, documentation of existing security measures, possibly preexisting risk treatment implementation plans, and the list of business processes. The output of the subprocess is a list of assets to be risk-managed together with a list of business processes related to these assets; a list of threats on these assets; a list of existing and planned security measures, their implementation and usage status; a list of vulnerabilities related to assets, threats and already installed security measures; a list of vulnerabilities that do not relate to any identified threat; and a list of incident scenarios with their consequences, related to assets and business processes.[31]

Two kinds of assets can be distinguished, namely *primary assets*, which include business processes and activities and information, and *supporting assets*, which include hardware, software, network, personnel, site, and the organization's structure. Hardware assets comprise data-processing equipment (transportable and fixed), peripherals, and media. Software assets comprise the operating system; service, maintenance or administration software; and application software. Network assets comprise medium and supports, passive or active relays, and communication interfaces. Personnel assets comprise decision makers, users, operation/maintenance staff, and developers. The site assets comprise the location (and its external environment, premises, zone, essential services, communication and utilities characteristics) and the organization (and its authorities, structure, the project or system organization and its subcontractors, suppliers and manufacturers).[32]

Threats are classified according to their type and to their origin. Threat types are physical damage (fire, water, pollution); natural events (climatic phenomenon, seismic phenomenon, volcanic phenomenon); loss of essential services (failure of air-conditioning, loss of power supply, failure of telecommunication equipment); disturbance due to radiation (electromagnetic radiation, thermal radiation, electromagnetic pulses); compromise of information (eavesdropping, theft of media or documents, retrieval of discarded or recycled media); technical failures (equipment failure, software malfunction, saturation of the information system); unauthorized actions (fraudulent copying of software, corruption of data, unauthorized use of equipment); and compromise of functions (error in use, abuse of rights, denial of actions).[33] Threats are classified according to origin into deliberate, accidental or environmental. A deliberate threat is an action aiming at information assets (remote spying, illegal processing of data); an accidental threat is an action that can accidentally damage information assets (equipment failure, software malfunction); and an environmental threat is any threat that is not based on human action (a natural event, loss of power supply). Note that a threat type may have multiple origins.

Vulnerabilities are classified according to the asset class they relate to. Therefore, vulnerabilities are

7	3	3	4	5	5	5	5	5	6
8	3	3	4	5	6	6	6	6	6
9	3	4	4	5	6	6	6	7	7
10	3	4	5	5	6	6	6	7	7

classified as hardware (susceptibility to humidity, dust, soiling; unprotected storage); software (no or insufficient software testing, lack of audit trail); network (unprotected communication lines, insecure network architecture); personnel (inadequate recruitment processes, lack of security awareness); site (location in an area susceptible to flood, unstable power grid); and organization (lack of regular audits, lack of continuity plans).[34]

Risk analysis is done either quantitatively or qualitatively. Qualitative analysis uses a scale of qualifying attributes to describe the magnitude of potential consequences (low, medium or high) and the likelihood that these consequences will occur. Quantitative analysis uses a scale with numerical values for both consequences and likelihood. In practice, qualitative analysis is used first, to obtain a general indication of the level of risk and to reveal the major risks. It is then followed by a quantitative analysis on the major risks identified.

Risk analysis involves a number of steps, namely assessment of consequences (through valuation of assets); assessment of incident likelihood (through threat and vulnerability valuation); and determination of the risk level. We discussed valuation of assets, threats, and vulnerabilities in an earlier section. Input to the subprocess is the output of the risk identification subprocess. Its output is a list of risks with value levels assigned.

34. ISO/IEC, "Information technology—security techniques—information security risk management," ISO/IEC 27005:2011 (E).

Having valuated assets, threats, and vulnerabilities, we should be able to calculate the resulting risk, if the function relating these to risk is known. Establishing an analytic function for this purpose is probably impossible and certainly ineffective. This is why, in practice, an empirical matrix is used for this purpose[35]. Such a matrix, an example of which is shown in Table 53.2, links asset values and threat and vulnerability levels to the resulting risk. In this example, asset values are expressed on a 0–10 scale, whereas threat and vulnerability levels are expressed on a Low-Medium-High scale. The risk values are expressed on a scale of 1 to 7. When linking the asset values and the threats and vulnerabilities, consideration needs to be given to whether the threat/vulnerability combination could cause problems to confidentiality, integrity, and/or availability. Depending on the results of these considerations, the appropriate asset value(s) should be chosen, that is, the one that has been selected to express the impact of a loss of confidentiality, or the one that has been selected to express the loss of integrity, or the one chosen to express the loss of availability. Using this method can lead to multiple risks for each of the assets, depending on the particular threat/vulnerability combination considered.[36]

35. British Standards Institute, "ISMSs—Part 3: Guidelines for information security risk management," BS 7799-3:2006.
36. British Standards Institute, "ISMSs—Part 3: Guidelines for information security risk management," BS 7799-3:2006.

Finally, the risk evaluation process receives as input the output of the risk analysis process. It compares the levels of risk against the risk evaluation criteria and risk acceptance criteria that were established within the context establishment process. The process uses the understanding of risk obtained by the risk assessment process to make decisions about future actions. These decisions include whether an activity should be undertaken and setting priorities for risk treatment. The output of the process is a list of risks prioritized according to the risk evaluation criteria, in relation to the incident scenarios that lead to those risks.

Risk Treatment

When the risk is calculated, the risk assessment process finishes. However, our actual ultimate goal is treating the risk. The risk treatment process aims at selecting security measures to reduce, retain, avoid, or transfer the risks and at defining a risk treatment plan. The process receives as input the output of the risk assessment process and produces as output the risk treatment plan and the residual risks subject to the acceptance decision by the management of the organization.

The options available to treat risk are to modify it, to retain it, to avoid it, or to share it. Combinations of these options are also possible. The factors that might influence the decision are the cost each time the incident related to the risk happens; how frequently it is expected to happen; the organization's attitude toward risk; the ease of implementation of the security measures required to treat the risk; the resources available; the current business/technology priorities; and organizational and management politics.[37]

For all those risks where the option to modify the risk has been chosen, appropriate security measures should be implemented to reduce the risks to the level that has been identified as acceptable, or at least as much as is feasible toward that level. These questions then arise: How much can we reduce the risk? Is it possible to achieve zero risk?

Zero risk is possible when either the cost of an incident is zero or when the likelihood of the incident occurring is zero. The cost of an incident is zero when the value of the implicated asset is zero or when the impact to the organization is zero. Therefore, if one or more of these conditions are found to hold during the risk assessment process, it is meaningless to take security measures. On the other hand, the likelihood of an incident occurring being zero is not possible, because the threats faced by an open system operating in a dynamic, hence highly variable, environment, as contemporary information systems do, and the causes that generate them are extremely complex; human behavior, which is extremely difficult to predict and model, plays a very important role in securing information systems; and the resources that a business or organization has at its disposal are finite.

When faced with a nonzero risk, our interest focuses on reducing the risk to acceptable levels. Because risk is a non-decreasing function in all its constituents, security measures can reduce it by reducing these constituents. Since the asset value cannot be directly reduced,[38] it is possible to reduce risk by reducing the likelihood of the threat occurring or the likelihood of the vulnerability being successfully exploited or the impact should the threat succeed. Which of these ways (or a combination of them) an organization chooses to adopt to protect its assets is a business decision and depends on the business requirements, the environment, and the circumstances in which the organization needs to operate. There is no universal or common approach to the selection of security measures. A possibility is to assign numerical values to the efficiency of each security measure, on a scale that matches that in which risks are expressed, and select all security measures that are relevant to the particular risk and have an efficiency score of at least equal to the value of the risk. Several sources provide lists of potential security measures.[39,40] Documenting the selected security measures is important in supporting certification and enables the organization to track the implementation of the selected security measures.

When considering modifying (reducing) a risk, several constraints may appear. These may be related to the timeframe; to financial or technical issues; to the way the organization operates or to its culture; to the environment within which the organization operates; to the applicable legal framework or to ethics; to the ease of use of the appropriate security measures; to the availability and suitability of personnel; or to the difficulties of integrating new and existing security measures. Due to the existence of these constraints, it is likely that some risks will exist for which either the organization cannot install appropriate security measures or for which the cost of

37. ISO/IEC, "Information technology—security techniques—information security risk management," ISO/IEC 27005:2011 (E).

38. As we will see later, it is possible to indirectly reduce the value of an asset. For example, if sensitive personal data are stored and the cost of protecting them is high, it is possible to decide that such data are too costly to continue storing. This constitutes a form of risk avoidance. As another example, we may decide that the cost for protecting our equipment is too high and to resort to outsourcing. This is a form of risk sharing.

39. ISO/IEC, "Information security management—specification with guidance for use," ISO 27001.

40. British Standards Institute, "Information technology—Security techniques—Information security incident management," BS ISO/IEC 17799:2005.

implementing appropriate measures outweighs the potential loss through the incident related to the risk occurring. In these cases, a decision may be made to retain the risk and live with the consequences if the incident related to the risk occurs. These decisions must be documented so that management is aware of its risk position and can knowingly retain the risk. The importance of this documentation has led risk acceptance to be identified as a separate process.[41] A special case where particular attention must be paid is when an incident related to a risk is deemed to be highly unlikely to occur but, if it occurred, the organization would not survive. If such a risk is deemed to be unacceptable but too costly to reduce, the organization could decide to share it.

Risk sharing is an option whereby it is difficult for the organization to reduce the risk to an acceptable level or the risk can be more economically shared with a third party. Risks can be shared using insurance. In this case, the question of what is a fair premium arises.[42] Another possibility is to use third parties or outsourcing partners to handle critical business assets or processes if they are suitably qualified for doing so. Combining both options is also possible; in this case, the fair premium may be determined.[43]

Risk avoidance describes any action where the business activities or ways to conduct business are changed to avoid any risk occurring. For example, risk avoidance can be achieved by not conducting certain business activities, by moving assets away from an area of risk, or by deciding not to process particularly sensitive information. Risk avoidance entails that the organization consciously accepts the impact likely to occur if an incident occurs. However, the organization chooses not to install the required security measures to reduce the risk. There are several cases where this option is exercised, particularly when the required measures contradict the culture and/or the policy of the organization.

After the risk treatment decision(s) have been taken, there will always be risks remaining. These are called *residual risks*. Residual risks can be difficult to assess, but at least an estimate should be made to ensure that sufficient protection is achieved. If the residual risk is unacceptable, the risk treatment process should be repeated.

41. ISO/IEC, "Information technology—security techniques—information security risk management," ISO/IEC 27005:2011 (E).

42. C. Lambrinoudakis, S. Gritzalis, P. Hatzopoulos, A. N. Yannacopoulos, and S. K. Katsikas, "A formal model for pricing information systems insurance contracts," *Computer Standards and Interfaces*, Vol. 27, pp. 521−532, 2005.

43. S. Gritzalis, A. N. Yannacopoulos, C. Lambrinoudakis, P. Hatzopoulos, S. K. Katsikas, "A probabilistic model for optimal insurance contracts against security risks and privacy violation in IT outsourcing environments," *International Journal of Information Security*, Vol. 6, pp. 197−211, 2007.

Once the risk treatment decisions have been taken, the activities to implement these decisions need to be identified and planned. The risk treatment plan needs to identify limiting factors and dependencies, priorities, deadlines and milestones, resources, including any necessary approvals for their allocation, and the critical path of the implementation.

Risk Communication and Consultation

Risk communication is a horizontal process that interacts bi-directionally with all other processes of risk management. Its purpose is to establish a common understanding of all aspects of risk among all the organization's stakeholders. Common understanding does not come automatically, since it is likely that perceptions of risk vary widely due to differences in assumptions, needs, concepts, and concerns. Establishing a common understanding is important, since it influences decisions to be taken and the ways in which such decisions are implemented. Risk communication must be made according to a well-defined plan that should include provisions for risk communication under both normal and emergency conditions.

Risk Monitoring and Review

Risk management is an ongoing, never-ending process that is assigned to an individual, a team, or an outsourced third party, depending on the organization's size and operational characteristics. Within this process, implemented security measures are regularly monitored and reviewed to ensure that they function correctly and effectively and that changes in the environment have not rendered them ineffective. Because over time there is a tendency for the performance of any service or mechanism to deteriorate, monitoring is intended to detect this deterioration and initiate corrective action. Maintenance of security measures should be planned and performed on a regular, scheduled basis.

The results from an original security risk assessment exercise need to be regularly reviewed for change, since there are several factors that could change the originally assessed risks. Such factors may be the introduction of new business functions, a change in business objectives and/or processes, a review of the correctness and effectiveness of the implemented security measures, the appearance of new or changed threats and/or vulnerabilities, or changes external to the organization. After all these different changes have been taken into account, the risk should be recalculated and *necessary* changes to the risk treatment decisions and security measures identified and documented.

Regular internal audits should be scheduled and should be conducted by an independent party that does

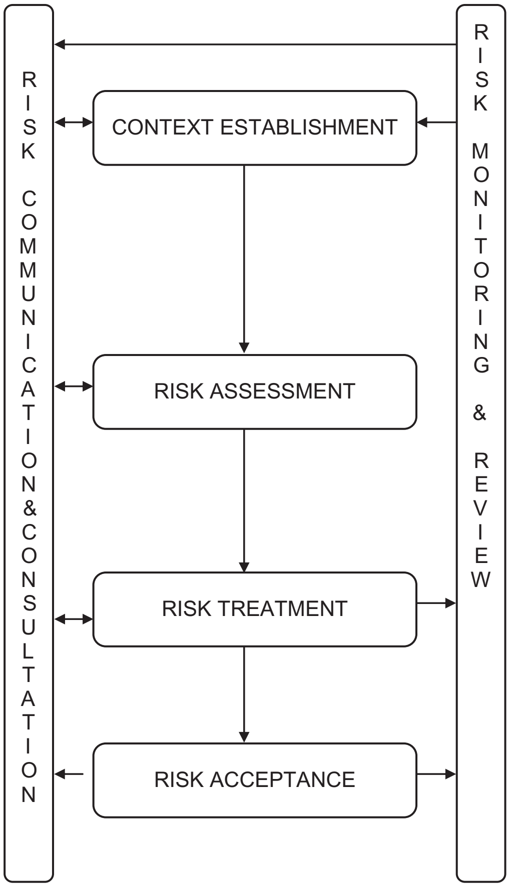

FIGURE 53.2 The risk management methodology.

not need to be from outside the organization. Internal auditors should not be under the supervision or control of those responsible for the implementation or daily management of the ISMS. Additionally, audits by an external body are not only useful, they are essential for certification.

Finally, complete, accessible, and correct documentation and a controlled process to manage documents are necessary to support the ISMS, although the scope and detail will vary from organization to organization. Aligning these documentation details with the documentation requirements of other management systems, such as ISO 9001, is certainly possible and constitutes good practice. Figure 53.2 pictorially summarizes the different processes within the risk management methodology, as we discussed earlier.

Integrating Risk Management into the System Development Life Cycle

Risk management must be totally integrated into the system development life cycle. This cycle consists of five phases: initiation; development or acquisition; implementation; operation or maintenance; and disposal. Within the initiation phase, identified risks are used to support the development of the system requirements, including security requirements and a security concept of operations. In the development or acquisition phase, the risks identified can be used to support the security analyses of the system that may lead to architecture and design tradeoffs during system development. In the implementation phase, the risk management process supports the assessment of the system implementation against its requirements and within its modeled operational environment. In the operation or maintenance phase, risk management activities are whenever major changes are made to a system in its operational environment. Finally, in the disposal phase, risk management activities are performed for system components that will be disposed of or replaced to ensure that the hardware and software are properly disposed of, that residual data is appropriately handled, and that system migration is conducted in a secure and systematic manner.[44]

Critique of Risk Management as a Methodology

Risk management as a scientific methodology has been criticized as being shallow. The main reason for this rather strong and probably unfair criticism is that risk management does not provide for feedback of the results of the selected security measures or of the risk treatment decisions. In most cases, even though the trend has already changed, information systems security is a low-priority project for management, until some security incident happens. Then, and only then, does management seriously engage in an effort to improve security measures. However, after a while, the problem stops being at the center of interest, and what remains is a number of security measures, some specialized hardware and software, and an operationally more complex system. Unless an incident happens again, there is no way for management to know whether their efforts were really worthwhile. After all, in many cases the information system had operated for years in the past without problems, without the security improvements that the security professionals recommended.

The risk management methodology, as has already been stated, is based on the scientific foundations of statistical decision making. The Bayes Theorem, on which the theory is based, pertains to the statistical revision of *a priori* probabilities, providing *a posteriori*

44. G. Stoneburner, A. Goguen and A. Feringa, *Risk Management Guide for Information Technology Systems*, National Institute of Standards and Technology, Special Publication SP 800-30, 2002.

probabilities, and is applied when a decision is sought based on imperfect information. In risk management, the decision for quantifying an event may be a function of additional factors, other than the probability of the event itself occurring. For example, the probability for a riot to occur may be related to the stability of the political system. Thus, the calculation of this probability should involve quantified information relevant to the stability of the political system. The overall model accepts the possibility that any information ("The political system is stable") may be inaccurate. In comparison to this formal framework, risk management, as applied by the security professionals, is simplistic. Indeed, by avoiding the complexity that accompanies the formal probabilistic modeling of risks and uncertainty, risk management looks more like a process that attempts to guess rather than formally predict the future on the basis of statistical evidence.

Finally, the risk management methodology is highly subjective in assessing the value of assets, the likelihood of threats occurring, the likelihood of vulnerabilities being successfully exploited by threats, and the significance of the impact. This subjectivity is frequently obscured by the formality of the underlying mathematical-probabilistic models, the systematic way in which most risk analysis methods work, and the objectivity of the tools that support these methods.

If indeed the skepticism about the scientific soundness of the risk management methodology is justified, the question: Why, then, has risk management as a practice survived so long? becomes crucial. There are several answers to this question.

Risk management is a very important instrument in designing, implementing, and operating secure information systems, because it systematically classifies and drives the process of deciding how to treat risks. In doing so, it facilitates better understanding of the nature and the operation of the information system, thus constituting a means for documenting and analyzing the system. Therefore, it is necessary for supporting the efforts of the organization's management to design, implement, and operate secure information systems.

Traditionally, risk management has been seen by security professionals as a means to justify to management the cost of security measures. Nowadays, it does not only do that, but it also fulfills legislative and/or regulatory provisions that exist in several countries, which demand information systems to be protected in a manner commensurate with the threats they face.

Risk management constitutes an efficient means of communication between technical and administrative personnel, as well as management, because it allows us to express the security problem in a language comprehensible by management, by viewing security as an investment that can be assessed in terms of cost/benefit analysis.[45] Additionally, it is quite flexible, so it can fit in several scientific frameworks and be applied either by itself or in combination with other methodologies. It is the most widely used methodology for designing and managing information systems security and has been successfully applied in many cases.

Finally, an answer frequently offered by security professionals is that there simply is no other efficient way to carry out the tasks that risk management does. Indeed, it has been proved in practice that by simply using methods of management science, law, and accounting, it is not possible to reach conclusions that can adequately justify risk treatment decisions.

Risk Management Methods

Many methods for risk management are available today. Most of them are supported by software tools. Selecting the most suitable method for a specific business environment and the needs of a specific organization is very important, albeit quite difficult, for a number of reasons[46]:

- There is a lack of a complete inventory of all available methods, with all their individual characteristics.
- There exists no commonly accepted set of evaluation criteria for risk management methods.
- Some methods only cover parts of the whole risk management process. For example, some methods only calculate the risk, without covering the risk treatment process. Some others focus on a small part of the whole process (e.g., disaster recovery planning). Some focus on auditing the security measures, and so on.
- Risk management methods differ widely in the analysis level that they use. Some use high-level descriptions of the information system under study; others call for detailed descriptions.
- Some methods are not freely available to the market, a fact that makes their evaluation very difficult, if at all possible.

The National Institute of Standards and Technology (NIST) compiled, in 1991, a comprehensive report on risk management methods and tools.[47] The European Commission, recognizing the need for a homogenized and software-supported risk management methodology

for use by European businesses and organizations, assigned, in 1993, a similar project to a group of companies. Part of this project's results was the creation of an inventory and the evaluation of all available risk management methods at the time.[48] In 2006 the European Network and Information Security Agency (ENISA) repeated the endeavor. Even though some results toward an inventory of risk management/risk assessment methods have been made available,[49] the process is still ongoing.[50] Some of the most widely used risk management methods[51] are briefly described in the sequel.

CRAMM (CCTA Risk Analysis and Management Methodology)[52] is a method developed by the British government organization CCTA (Central Communication and Telecommunication Agency), now renamed the Office of Government Commerce (OGC). CRAMM was first released in 1985. At present CRAMM is the U.K. government's preferred risk analysis method, but CRAMM is also used in many countries outside the U.K. CRAMM is especially appropriate for large organizations, such as government bodies and industry. CRAMM provides a staged and disciplined approach embracing both technical and non-technical aspects of security. To assess these components, CRAMM is divided into three stages: asset identification and valuation; threat and vulnerability assessment; and countermeasure selection and recommendation. CRAMM enables the reviewer to identify the physical, software, data, and location assets that make up the information system. Each of these assets can be valued. Physical assets are valued in terms of their replacement cost. Data and software assets are valued in terms of the impact that would result if the information were to be unavailable, destroyed, disclosed, or modified. CRAMM covers the full range of deliberate and accidental threats that may affect information systems. This stage concludes by calculating the level of risk. CRAMM contains a very large countermeasure library consisting of over 3000 detailed countermeasures organized into over 70 logical groupings. The CRAMM software uses the measures of risks determined during the previous stage and compares them against the security level (a threshold level associated with each countermeasure) to identify whether the risks are sufficiently large to justify the installation of a particular countermeasure. CRAMM provides a series of help facilities, including backtracking, what-if scenarios, prioritization functions, and reporting tools, to assist with the implementation of countermeasures and the active management of the identified risks. CRAMM is ISO/IEC 17799, ISO/IEC 27001, Gramm-Leach-Bliley Act (GLBA), and Health Insurance Portability and Accountability Act (HIPAA) compliant.

MAGERIT is an open methodology for Risk Analysis and Management, developed by the Spanish Ministry of Public Administration and offered as a framework and guide to the Public Administration. Given its open nature, it is also used outside the Administration. MAGERIT was first released in 1997. The current version v2 was published in 2005 and is structured into three books. Book I (Methodology) describes the core steps and basic tasks to carry out a project for risk analysis and management; the formal description of the project; the application to the development of information systems and it provides a large number of practical clues, as well as the theoretical foundations, together with some other complementary information. Book II (Catalogue of elements) provides standard elements and criteria for information systems and risk modeling: asset classes, valuation dimensions, valuation criteria, typical threats, and safeguards to be considered; it also describes the reports containing the findings and conclusions (value model, risk map, safeguard evaluation, risk status, deficiencies report and security plan), thus contributing to achieve uniformity. Book III (Practical techniques) describes techniques frequently used to carry out risk analysis and management projects such as: tabular and algorithmic analysis; threat trees, cost-benefit analysis, dataflow diagrams, process charts, graphical techniques, project planning, working sessions (interviews, meetings, presentations), and Delphi analysis.[53] The application of MAGERIT can be supported by the software PILAR / EAR, which exploits and increases its potentialities and effectiveness.[54]

The methodological approach offered by EBIOS (Expression des Besoins et Identification des Objectifs de Sécurité)[55] provides a global and consistent view of information systems security. It was first released in 1995. The method takes into account all technical entities and nontechnical entities. It allows all personnel using the information system to be involved in security issues and offers a dynamic approach that encourages interaction among the organization's various jobs and functions by examining the complete life cycle of the system. Promoted by the DCSSI (Direction Centrale de la Sécurité des Systèmes d' Information) of the French government and recognized by the French administrations, EBIOS is also a reference in the private sector and outside France. The EBIOS approach consists of five phases. Phase 1 deals with context analysis in terms of global business process dependency on the information system. Security needs analysis and threat analysis are conducted in Phases 2 and 3. Phases 4 and 5 yield an objective diagnostic on risks. The necessary and sufficient security objectives (and further security requirements) are then stated, proof of coverage is furnished, and residual risks made explicit. Local standard bases (German IT Grundschutz) are easily added on to its internal knowledge bases and catalogues of best practices. EBIOS is supported by a software tool developed by the Central Information Systems Security Division (France). The tool helps the user to produce all risk analysis and management steps according to the EBIOS method and allows all the study results to be recorded and the required summary documents to be produced. EBIOS is compliant with ISO/IEC 27001, ISO/IEC 13335 (GMITS), ISO/IEC 15408 (Common Criteria), ISO/IEC 17799, and ISO/IEC 21827 and consistent with the ISO/IEC 31000, ISO/IEC 27005 and ISO/IEC 27001 standards.

The Information Security Forum's (ISF) Standard of Good Practice[56] provides a set of high-level principles and objectives for information security together with associated statements of good practice. The Standard of Good Practice is split into five distinct aspects, each of which covers a particular type of environment. These are security management; critical business applications; computer installations; networks; and systems development. FIRM (Fundamental Information Risk Management) is a detailed method for monitoring and controlling information risk at the enterprise level. It has been developed as a practical approach to monitoring the effectiveness of information security. As such, it enables information risk to be managed systematically across enterprises of all sizes. It includes comprehensive implementation guidelines, which explain how to gain support for the approach and get it up and running. The Information Risk Scorecard is an integral part of FIRM. The Scorecard is a form used to collect a range of important details about a particular information resource such as the name of the owner, criticality, level of threat, business impact, and vulnerability. The ISF's Information Security Status Survey is a comprehensive risk management tool that evaluates a wide range of security measures used by organizations to control the business risks associated with their IT-based information systems. SARA (Simple to Apply Risk Analysis) is a detailed method for analyzing information risk in critical information systems. SPRINT (Simplified Process for Risk Identification) is a relatively quick and easy-to-use method for assessing business impact and for analyzing information risk in important but not critical information systems. The full SPRINT method is intended for application to important, but not critical, systems. It complements the SARA method, which is better suited to analyzing the risks associated with critical business systems. SPRINT first helps decide the level of risk associated with a system. After the risks are fully understood, SPRINT helps determine how to proceed and, if the SPRINT process continues, culminates in the production of an agreed plan of action for keeping risks within acceptable limits. SPRINT can help identify the vulnerabilities of existing systems and the safeguards needed to protect against them; and define the security requirements for systems under development and the security measures needed to satisfy them. The method is compliant to ISO/IEC 17799. The method was revised in 2011. The 2011 version is aligned with the requirements for an Information Security Management System (ISMS) set out in ISO 27001 and provides a wider and deeper coverage of ISO 27002 controls topics. It particularly covers many new topics, such as cloud computing, information leakage, consumer devices and security governance. Further, the 2011 Standard provides full coverage of COBIT v4 topics, and offers substantial alignment with other relevant standards and legislation such as PCI/DSS and the Sarbanes Oxley Act.

IT-Grundschutz (IT Baseline protection)[57] provides a method for an organization to establish an ISMS. It was first released in 1994. The full method, to which we will come back in Section 5, describes an ISMS comprising a governance structure and suite of information security

56. Information Security Forum, *The standard of good practice for information security*, 2007 and 2011 (available at https://www.securityforum.org/downloadresearch/downloadsogp/, accessed August 23, 2012).

57. "IT-Grundschutz", © Federal Office for Information Security (BSI). All rights reserved [https://www.bsi.bund.de/ContentBSI/EN/Topics/ITGrundschutz/itgrundschutz.html], 2012.

controls ranging from technological, organizational and sociological to infrastructural (physical) in nature. In its present form the IT Grundschutz comprises several parts, so the methods are separate from the catalog of threats. The part describing the risk analysis method is BSI Standard 100-3 "Risk Analysis Based on IT-Grundschutz" that uses the catalogs to specify security controls for 'normal' systems that are assumed to have 'normal' risks, using risk analysis only to identify additional risk and control requirements for 'high' or 'very high' systems. The IT security process suggested by IT-Grundschutz consists of the following steps: initialization of the process; definition of IT security goals and business environment; establishment of an organizational structure for IT security; provision of necessary resources; creation of the IT security concept; IT structure analysis; assessment of protection requirements; modeling; IT security check; supplementary security analysis; implementation planning and fulfillment; maintenance, monitoring, and improvement of the process; and IT-Grundschutz Certification (optional). IT-Grundschutz is supported by a software tool named *Gstool*[58] that has been developed by the Federal Office for Information Security (BSI). The method is compliant with ISO/IEC 17799 and ISO/IEC 27001.

MEHARI (Méthode Harmonisée d'Analyse de Risques Informatiques)[59] is a method designed by security experts of the CLUSIF (Club de la Sécurité Informatique Français) that replaced the earlier CLUSIF-sponsored MARION and MELISA methods. It was first released in 1996. It proposes an approach for defining risk reduction measures suited to the organization objectives. MEHARI provides a risk assessment model and modular components and processes. It enhances the ability to discover vulnerabilities through audit and to analyze risk situations. MEHARI includes formulas facilitating threat identification and threat characterization and optimal selection of corrective actions. MEHARI allows for providing accurate indications for building security plans, based on a complete list of vulnerability control points and an accurate monitoring process in a continual improvement cycle. It is compliant with ISO/IEC 17799 and ISO/IEC 13335.

The OCTAVE (Operationally Critical Threat, Asset, and Vulnerability Evaluation)[60] method, developed by the Software Engineering Institute of Carnegie-Mellon University, defines a risk-based strategic assessment and planning technique for security. It was first released in 1999. OCTAVE is self-directed in the sense that a small team of people from the operational (or business) units and the IT department work together to address the security needs of the organization. The team draws on the knowledge of many employees to define the current state of security, identify risks to critical assets, and set a security strategy. OCTAVE is different from typical technology-focused assessments in that it focuses on organizational risk and strategic, practice-related issues, balancing operational risk, security practices, and technology. The OCTAVE method is driven by operational risk and security practices. Technology is examined only in relation to security practices. OCTAVE-S is a variation of the method tailored to the limited means and unique constraints typically found in small organizations (less than 100 people). OCTAVE Allegro is tailored for organizations focused on information assets and a streamlined approach. The Octave Automated Tool has been implemented by the Advanced Technology Institute (ATI) to help users with the implementation of the OCTAVE method.

Callio Secura 17799[61] was first released in 2001. It is a multiuser Web application with database support that lets the user implement and certify an ISMS and guides the user through each of the steps leading to ISO 27001/17799 compliance and BS 7799-2 certification. Moreover, it provides document management functionality as well as customization of the tool's databases. It also allows carrying out audits for other standards, such as COBIT, HIPAA, and Sarbanes-Oxley, by importing the user's own questionnaires. Callio Secura is compliant with ISO/IEC 17799 and ISO/IEC 27001.

COBRA[62] is a standalone application for risk management from C&A Systems Security. It is a questionnaire-based Windows PC tool, using expert system principles and a set of extensive knowledge bases. It has also embraced the functionality to optionally deliver other security services, such as checking compliance with the ISO 17799 security standard or with an organization's own security policies. It can be used for identification of threats and vulnerabilities; it measures the degree of actual risk for each area or aspect of a system and directly links this to the potential business impact. It offers detailed solutions and recommendations to reduce the risks and provides business as well as technical reports. It is compliant with ISO/IEC 17799.

Alion's product CounterMeasures[63] performs web-based enterprise risk management based on the US-NIST 800 series and OMB Circular A-130 USA standards. The user standardizes the evaluation criteria and, using a "tailor-made" assessment checklist, the software provides objective evaluation criteria for determining security posture and/or compliance. CounterMeasures is available in both networked and desktop configurations. It is compliant with the NIST 800 series and OMB Circular A-130 USA standards.

Proteus[64] is a product suite from InfoGov. It was first released in 1999. Through its components the user can perform gap analysis against standards such as ISO 17799 or create and manage an ISMS according to ISO 27001 (BS 7799-2). Proteus Enterprise is a fully integrated Web-based Information Risk Management, Compliance and Security solution that is fully scalable. Using Proteus Enterprise, companies can perform any number of online compliance audits against any standard and compare between them. They can then assess how deficient compliance security measures affect the company both financially and operationally by mapping them onto its critical business processes. Proteus then identifies risks and mitigates those risks by formulating a work plan, maintains a current and demonstrable compliance status to the regulators and senior management alike. The system works with the company's existing infrastructure and uses RiskView to bridge the gap between the technical/regulatory community and senior management. Proteus is a comprehensive system that includes online compliance and gap analysis, business impact, risk assessment, business continuity, incident management, asset management, organization roles, policy repository, and action plans. Its compliance engine supports any standard (international, industry, and corporate specific) and is supplied with a choice of comprehensive template questionnaires. The system is fully scalable and can size from a single user up to the largest of multinational organizations. The product maintains a full audit trail. It can perform online audits for both internal departments and external suppliers. It is compliant with ISO/IEC 17799 and ISO/IEC 27001.

CORAS[65] is a method for conducting security risk analysis. CORAS provides a customized language for threat and risk modeling, and comes with detailed guidelines explaining how the language should be used to capture and model relevant information during the various stages of the security analysis. In this respect CORAS is model-based. The Unified Modelling Language (UML) is typically used to model the target of the analysis. For documenting intermediate results and for presenting the overall conclusions special CORAS diagrams are used, which are inspired by UML. The CORAS method provides a computerized tool designed to support documenting, maintaining and reporting analysis results through risk modeling. In the CORAS method a security risk analysis is conducted in eight steps: Preparations for the analysis; Customer presentation of the target; Refining the target description using asset diagrams; Approval of the target description; Risk identification using threat diagrams; Risk estimation using threat diagrams; Risk evaluation using risk diagrams; and risk treatment using treatment diagrams. The method is supported by a software tool.[66]

RiskWatch for Information Systems & ISO 17799[67] is the RiskWatch company's solution for information system risk management. Other relevant products in the same suite are RiskWatch for Financial Institutions, RiskWatch for HIPAA Security, RiskWatch for Physical & Homeland Security, RiskWatch for University and School Security, and RiskWatch for NERC (North American Electric Reliability Corporation) and C-TPAT-Supply Chain. The RiskWatch for Information Systems & ISO 17799 tool conducts automated risk analysis and vulnerability assessments of information systems. All RiskWatch software is fully customizable by the user. It can be tailored to reflect any corporate or government policy, including incorporation of unique standards, incident report data, penetration test data, observation, and country-specific threat data. Every product includes both information security as well as physical security. Project plans and a simple workflow make it easy to create accurate and supportable risk assessments. The tool includes security measures from the ISO 17799 and USNIST 800-26 standards, with which it is compliant.

The SBA (Security by Analysis) method[68] is a concept that has existed since the beginning of the 1980s. It is more of a way of looking at analysis and security work in computerized businesses than a fully developed method. It could be called the "human model" concerning risk and vulnerability analyses. The human model implies a very strong confidence in knowledge among staff and

individuals within the analyzed business or organizations. It is based on the idea that it is those who work with the everyday problems, regardless of position, who are better qualified to pinpoint the most important problems and to suggest the solutions. SBA is supported by three software tools. Every tool implements its own method, but they are all based on the same concept: gathering a group of people who represent the necessary breadth of knowledge. SBA Check is primarily a tool for anyone working with or responsible for information security issues. The role of analysis leader is central to the use of SBA Check. The analysis leader is in charge of ensuring that the analysis participants' knowledge of the operation is brought to bear during the analysis process in a way that is relevant, so that the description of the current situation and opportunities for improvement retain their consistent quality. SBA Scenario is a tool that helps evaluate business risks methodically through quantitative risk analysis. The tool also helps evaluate which actions are correct and financially motivated through risk management. SBA Project is an IT support tool and a method that helps identify conceivable problems in a project as well as providing suggestions for conceivable measures to deal with those problems. The analysis participants' views and knowledge are used as a basis for providing a good picture of the risk in the project.

4. RISK MANAGEMENT LAWS AND REGULATIONS

Many nations have adopted laws and regulations containing clauses that, directly or indirectly, pertain to aspects of information systems risk management. Similarly, a large number of international laws and regulations exist. In the following, a brief description of such documents with an international scope, directly relevant to information systems risk management,[69] is given.

The "Regulation (EC) No 45/2001 of the European Parliament and of the Council of 18 December 2000 on the protection of individuals with regard to the processing of personal data by the Community institutions and bodies and on the free movement of such data"[70] requires that any personal data processing activity by Community institutions undergoes a prior risk analysis to determine the privacy implications of the activity and to determine the appropriate legal, technical, and organizational measures to protect such activities. It also stipulates that such activity is effectively protected by measures, which must be state of the art, keeping into account the sensitivity and privacy implications of the activity. When a third party is charged with the processing task, its activities are governed by suitable and enforced agreements. Furthermore, the regulation requires the European Union's (EU) institutions and bodies to take similar precautions with regard to their telecommunications infrastructure, and to properly inform the users of any specific risks of security breaches.[71]

The European Commission's Directive on Data Protection went into effect in October 1998 and prohibits the transfer of personal data to non-EU nations that do not meet the European "adequacy" standard for privacy protection. The United States takes a different approach to privacy from that taken by the EU; it uses a sectoral approach that relies on a mix of legislation, regulation, and self-regulation. The EU, however, relies on comprehensive legislation that, for example, requires creation of government data protection agencies, registration of data bases with those agencies, and in some instances prior approval before personal data processing may begin. The Safe Harbor Privacy Principles[72] aim at bridging this gap by providing that an EU-based entity self-certifies its compliance with them.

The "Commission Decision of 15 June 2001 on standard contractual clauses for the transfer of personal data to third countries, under Directive 95/46/EC", the "Commission Decision of 27 December 2004 amending Decision 2001/497/EC as regards the introduction of an alternative set of standard contractual clauses for the transfer of personal data to third countries" and the : Commission Decision of 5 February 2010 on standard contractual clauses for the transfer of personal data to processors established in third countries under Directive 95/46/EC of the European Parliament and of the Council"[73] provide a set of voluntary model clauses that can be used to export personal data from a data controller who is subject to EU data protection rules to a data processor outside the EU who is not subject to these rules or to a similar set of adequate rules. Upon acceptance of the

model clauses, the data controller must warrant that the appropriate legal, technical, and organizational measures to ensure the protection of the personal data are taken. Furthermore, the data processor must agree to permit auditing of its security practices to ensure compliance with applicable European data protection rules.[74]

The Health Insurance Portability and Accountability Act of 1996[75] is a U.S. law with regard to health insurance coverage, electronic health, and requirements for the security and privacy of health data. Title II of HIPAA, known as the Administrative Simplification (AS) provisions, requires the establishment of national standards for electronic health care transactions and national identifiers for providers, health-insurance plans, and employers. Per the requirements of Title II, the Department of Health and Human Services has promulgated five rules regarding Administrative Simplification: the Privacy Rule, the Transactions and Code Sets Rule, the Security Rule, the Unique Identifiers Rule, and the Enforcement Rule. The standards are meant to improve the efficiency and effectiveness of the U.S. health care system by encouraging the widespread use of electronic data interchange.

The "Directive 2002/58/EC of the European Parliament and of the Council of 12 July 2002 concerning the processing of personal data and the protection of privacy in the electronic communications sector (Directive on privacy and electronic communications)"[76] requires that any provider of publicly available electronic communications services takes the appropriate legal, technical and organizational measures to ensure the security of its services; informs his subscribers of any particular risks of security breaches; and takes the necessary measures to prevent such breaches, and indicates the likely costs of security breaches to the subscribers.[77]

The "Directive 2006/24/EC of the European Parliament and of the Council of 15 March 2006 on the retention of data generated or processed in connection with the provision of publicly available electronic communications services or of public communications networks and amending Directive 2002/58/EC"[78] requires the affected providers of publicly accessible electronic telecommunications networks to retain certain communications data to be specified in their national regulations, for a specific amount of time, under secured circumstances in compliance with applicable privacy regulations; to provide access to this data to competent national authorities; to ensure data quality and security through appropriate technical and organizational measures, shielding it from access by unauthorized individuals; to ensure its destruction when it is no longer required; and to ensure that stored data can be promptly delivered on request from the competent authorities.[79]

The "Regulation (EC) No 1907/2006 of the European Parliament and of the Council of 18 December 2006 concerning the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH), establishing a European Chemicals Agency, amending Directive 1999/45/EC and repealing Council Regulation (EEC) No 793/93 and Commission Regulation (EC) No 1488/94 as well as Council Directive 76/769/EEC and Commission Directives 91/155/EEC, 93/67/EEC, 93/105/EC and 2000/21/EC"[80] implants risk management obligations by imposing a reporting obligation on producers and importers of articles covered by the regulation, with regard to the qualities of certain chemical substances, which includes a risk assessment and obligation to examine how such risks can be managed. This information is to be registered in a central database. It also stipulates that a Committee for Risk Assessment within the European Chemicals Agency established by the Regulation is established and requires that the information provided is kept up to date with regard to potential risks to human health or the environment, and that such risks are adequately managed.[81]

The "Council Framework Decision 2005/222/JHA of 24 February 2005 on attacks against information systems"[82] contains the conditions under which legal liability can be imposed on legal entities for conduct of certain natural persons of authority within the legal entity. Thus, the Framework decision requires that the conduct of such figures within an organization is adequately monitored, also because the decision states that a legal entity can be held liable for acts of omission in this regard. Additionally, the decision defines a series of criteria under which jurisdictional competence can be established. These include the competence of a jurisdiction when a criminal act is conducted against an information system within its borders.[83]

The "OECD Guidelines for the Security of Information Systems and Networks: Towards a Culture of Security" (25 July 2002)[84] aim to promote a culture of security; to raise awareness about the risk to information systems and networks (including the policies, practices, measures, and procedures available to address those risks and the need for their adoption and implementation); to foster greater confidence in information systems and networks and the way in which they are provided and used; to create a general frame of reference; to promote cooperation and information sharing; and to promote the consideration of security as an important objective. The guidelines state nine basic principles underpinning risk management and information security practices. No part of the text is legally binding, but noncompliance with any of the principles is indicative of a breach of risk management good practices that can potentially incur liability.[85]

The "Basel Committee on Banking Supervision—Risk Management Principles for Electronic Banking"[86] identifies 14 Risk Management Principles for Electronic Banking to help banking institutions expand their existing risk oversight policies and processes to cover their e-banking activities. The Risk Management Principles fall into three broad, and often overlapping, categories of issues that are grouped to provide clarity: board and management oversight; security controls; and legal and reputational risk management. The Risk Management Principles are not put forth as absolute requirements or even "best practice," nor do they attempt to set specific technical solutions or standards relating to e-banking. Consequently, the Risk Management Principles and sound practices are expected to be used as tools by national supervisors and to be implemented with adaptations to reflect specific national requirements and individual risk profiles where necessary.

The "Commission Recommendation 87/598/EEC of 8 December 1987, concerning a European code of conduct relating to electronic payments"[87] provides a number of general nonbinding recommendations. This includes an obligation to ensure that privacy is respected and that the system is transparent with regard to potential security or confidentiality risks, which must obviously be mitigated by all reasonable means.[88]

The "Public Company Accounting Reform and Investor Protection Act of 30 July 2002" (commonly referred to as *Sarbanes-Oxley* and often abbreviated to *SOX* or *Sarbox*)[89] even though indirectly relevant to risk management, is discussed here due to its importance. The Act is a U.S. federal law passed in response to a number of major corporate and accounting scandals including those affecting Enron, Tyco International, and WorldCom (now MCI). These scandals resulted in a decline of public trust in accounting and reporting practices. The legislation is wide ranging and establishes new or enhanced standards for all U.S. public company boards, management, and public accounting firms. Its provisions range from additional Corporate Board responsibilities to criminal penalties, and require the Securities and Exchange Commission (SEC) to implement rulings on requirements to comply with the new law. The first and most important part of the Act

88. J. Dumortier and H. Graux, "Risk management/risk assessment in European regulation, international guidelines and codes of practice," ENISA, June 2007 (available at http://www.enisa.europa.eu/activities/risk-management/current-risk/laws-regulation/downloads/risk-management-risk-assessment-in-european-regulation-international-guidelines-and-codes-of-practice, accessed August 24, 2012).

89. US Public Law 107-204-July 30, 2002, 116 STAT.745 (available at http://www.gpo.gov/fdsys/pkg/PLAW-107publ204/pdf/PLAW-107publ204.pdf, accessed August 24, 2012).

establishes a new quasi-public agency, the Public Company Accounting Oversight Board (www.pcaobus.org), which is charged with overseeing, regulating, inspecting, and disciplining accounting firms in their roles as auditors of public companies. The Act also covers issues such as auditor independence, corporate governance and enhanced financial disclosure.

The "Office of the Comptroller of the Currency (OCC) – Electronic Banking Guidance,"[90] is fairly high level. And, it should be indicative of the subject matter to be analyzed and assessed by banking institutions, rather than serving as a yardstick to identify actual problems.[91]

The "Payment Card Industry (PCI) Security Standards Council—Data Security Standard (DSS)"[92] provides central guidance allowing financial service providers relying on payment cards to implement the necessary policies, procedures, and infrastructure to adequately safeguard their customer account data. PCI DSS has no formal binding legal power. Nevertheless, considering its origins and the key participants, it holds significant moral authority, and noncompliance with the PCI DSS by a payment card service provider may be indicative of inadequate risk management practices.[93]

The "Directive 2002/65/EC of the European Parliament and of the Council of 23 September 2002 concerning the distance marketing of consumer financial services and amending Council Directive 90/619/EEC and Directives 97/7/EC and 98/27/EC (the 'Financial Distance Marketing Directive')"[94] requires that, as a part of the minimum information to be provided to a consumer prior to concluding a distance financial services contract, the consumer must be clearly and comprehensibly informed of any specific risks related to the service concerned.[95]

5. RISK MANAGEMENT STANDARDS

Various national and international, de jure, and de facto standards exist that are related, directly or indirectly, to information systems risk management. In the following, we briefly describe the most important international standards that are directly related to risk management.

The ISO/IEC 27000 series of standards has been reserved for a family of information security management standards derived from British Standard BS 7799. Several standards within the series have already been published; others are in various stages of development. A comprehensive presentation and discussion of these standards is provided by the ISO27001 security home[96]. Within this series, the "ISO/IEC 27001:2005—Information technology—Security techniques—Information security management systems—Requirements" standard[97] is designed to ensure the selection of adequate and proportionate security measures that protect information assets and give confidence to interested parties. The standard covers all types of organizations (commercial enterprises, government agencies, not-for-profit organizations) and specifies the requirements for establishing, implementing, operating, monitoring, reviewing, maintaining, and improving a documented ISMS within the context of the organization's overall business risks. Further, it specifies requirements for the implementation of security measures customized to the needs of individual organizations or parts thereof. Its application in practice is often combined with related standards, such as BS 7799-3:2006 which provides additional guidance to support the requirements given in ISO/IEC 27001:2005.

The "ISO/IEC 27005:2011 – Information technology – Security techniques – Information security risk management" standard[98] provides guidelines for information security risk management. It supports the general concepts specified in ISO/IEC 27001 and is designed to assist the satisfactory implementation of information security based on a risk management approach. ISO/IEC 27005:2011 is

applicable to all types of organizations (commercial enterprises, government agencies, non-profit organizations) which intend to manage risks that could compromise the organization's information security. ISO/IEC 27005 revised and superseded the Management of Information and Communications Technology Security (MICTS) standards ISO/IEC TR 13335-3:1998 plus ISO/IEC TR 13335-4:2000. The standard describes the risk management methodology, without specifying, recommending or even naming any specific method.

The "ISO 31000:2009 Risk management – principles and guidelines" standard provides principles and generic guidelines on risk management.[99] The standard is not sector or industry-specific, and it can be used by any public, private or community enterprise, association, group or individual. It can be applied to any type of risk, whatever its nature, whether having positive or negative consequences. This also means that the standard is not specific to information security or even to IT risks. It is intended that ISO 31000:2009 be utilized to harmonize risk management processes in existing and future standards. It provides a common approach in support of standards dealing with specific risks and/or sectors, and does not replace those standards.

The IEC 31010:2009 "Risk management – risk assessment techniques" is a supporting standard for ISO 31000 and provides guidance on selection and application of systematic techniques for risk assessment. The standard treats risk assessment as an integral part of risk management, helping managers understand risks that could affect the achievement of business objectives and assess the adequacy and effectiveness of various risk mitigation controls. It covers risk assessment concepts as well as processes and a range of techniques.[100]

The ISO Guide 73:2009 provides the definitions of generic terms related to risk management. It aims to encourage a mutual and consistent understanding of, and a coherent approach to, the description of activities relating to the management of risk, and the use of uniform risk management terminology in processes and frameworks dealing with the management of risk. For principles and guidelines on risk management, reference is made to ISO 31000:2009.[101]

The "BS 7799-3:2006—Information security management systems—Guidelines for information security risk management" standard[102] was the predecessor of ISO/IEC 27005. It gives guidance to support the requirements given in BS ISO/IEC 27001:2005 regarding all aspects of an ISMS risk management cycle and is therefore typically applied in conjunction with this standard in risk assessment practices. This includes assessing and evaluating the risks, implementing security measures to treat the risks, monitoring and reviewing the risks, and maintaining and improving the system of risk treatment. The focus of this standard is effective information security through an ongoing program of risk management activities. This focus is targeted at information security in the context of an organization's business risks. With the proliferation of ISO/IEC 27005, it is expected that BS 7799 -3 will eventually be withdrawn.

In Section 3 we discussed BSI Standard 100-3, i.e. the part of IT-Grundschutz (IT Baseline protection)[103] that describes the risk analysis method. BSI Standard 100-1 Information Security Management Systems (ISMS) is an overview of the IT-Grundshutz approach to developing and implementing an ISMS. BSI Standard 100-2 IT-Grundschutz Methodology is basically about governance of information security within the organization using an ISMS. BSI Standard 100-4 *Business Continuity Management* explains how to establish and maintain a BCM system. BSI IS audit guideline *Information Security Audit (IS Audit) - a guideline for IS audits based on IT-Grundschutz* is primarily aimed at IS auditors working for German federal agencies. IT-Grundschutz Catalogues contains detailed advice on information security threats, controls etc.

The "ISF Standard of Good Practice" standard[104] which we discussed as a risk management method in Section 3, is a commonly quoted source of good practices and serves as a resource for the implementation of information security policies and as a yardstick for auditing such systems and/or the surrounding practices.[105] The standard covers six distinct aspects of information security, each of which relates to a particular type of environment. The standard focuses on how information security supports an organization's key business processes.

Graux, "Risk management/risk assessment in European regulation, international guidelines and codes of practice," ENISA, June 2007 (available at http://www.enisa.europa.eu/activities/risk-management/current-risk/laws-regulation/downloads/risk-management-risk-assessment-in-european-regulation-international-guidelines-and-codes-of-practice, accessed August 24, 2012).

organizations" guide[106] is intended to help federal managers implement an ongoing information security risk assessment process by providing examples, or case studies, of practical risk assessment procedures that have been successfully adopted by four organizations known for their efforts to implement good risk assessment practices. More important, it identifies, based on the case studies, factors that are important to the success of any risk assessment program, regardless of the specific methodology employed.

The U.S. NIST SP 800-30 "Risk management guide for information technology systems"[107] developed by NIST in 2002, provides a common foundation for experienced and inexperienced, technical, and non-technical personnel who support or use the risk management process for their IT systems. Its guidelines are for use by federal organizations which process sensitive information and are consistent with the requirements of OMB Circular A-130, Appendix III. The guidelines may also be used by nongovernmental organizations on a voluntary basis, even though they are not mandatory and binding standards.

Finally, the U.S. NIST SP 800-39 "Managing Information Security Risk: Organization, Mission and Information System View" standard[108] provides guidelines for managing risk to organizational operations, organizational assets, individuals, other organizations, and the nation resulting from the operation and use of information systems. It provides a structured yet flexible approach for managing that portion of risk resulting from the incorporation of information systems into the mission and business processes of organizations.

6. SUMMARY

The information systems risk management methodology was developed with an eye to guiding the design and the management of security of an information system within the framework of an organization. It aims at analyzing and assessing the factors that affect risk, to subsequently treat the risk, and to continuously monitor and review the security plan. Central concepts of the methodology are those of the threat, the vulnerability, the asset, the impact, and the risk. The operational relationship of these concepts materializes when a threat exploits one or more vulnerabilities to harm assets, an event that will impact the organization. Once the risks are identified and assessed, they must be treated, that is, modified, shared, avoided, or retained. Treating the risks is done on the basis of a carefully designed security plan, which must be continuously monitored, reviewed, and amended as necessary. Many methods implementing the whole or parts of the risk management methodology have been developed. Even though most of them follow closely the methodology as described in pertinent international standards, they differ considerably in both their underlying philosophy and in their specific steps. The risk management methodology has been and is being applied internationally with considerable success and enjoys universal acceptance. However, it does suffer several disadvantages that should be seriously considered in the process of applying it. Particular attention must be paid to the subjectivity of its estimates, which is often obscured by the formality of the underlying probabilistic models and by the systematic nature of most of the risk management methods. Subjectivity in applying the methodology is unavoidable and should be accepted and consciously managed. A number of international laws and regulations contain provisions for information system risk management, in addition to national provisions. The risk management methodology is standardized by international organizations.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Information security risk "is measured in terms of a combination of the likelihood of an event and not its consequence."
2. True or False? The likelihood of a security incident occurring is a function of the likelihood that a threat appears and of the likelihood that the threat can successfully exploit the relevant system vulnerabilities.
3. True or False? The term *methodology* means an organized set of principles and rules that drives action in a particular field of knowledge.
4. True or False? The context establishment process receives as input all relevant information about the organization.
5. True or False? Risk identification seeks to determine what could happen to cause a potential loss and to gain insight into how, where, and why the loss might happen.

Multiple Choice

1. What are classified according to the asset class they relate to?
   - **A.** Qualitative analysis
   - **B.** Vulnerabilities
   - **C.** Promotional email
   - **D.** Malformed request DoS
   - **E.** Data controller
2. When the risk is calculated, the _____________ process finishes.
   - **A.** Network attached storage (NAS)
   - **B.** Risk assessment
   - **C.** Valid
   - **D.** Load-Based DoS
   - **E.** Bait
3. What is a horizontal process that interacts bi-directionally with all other processes of risk management.
   - **A.** Data minimization
   - **B.** Fabric
   - **C.** Target access
   - **D.** Risk communication
   - **E.** Security
4. What is an ongoing, never-ending process that is assigned to an individual, a team, or an outsourced third party, depending on the organization's size and operational characteristics?
   - **A.** Risk management
   - **B.** Greedy strategy
   - **C.** Ports
   - **D.** SAN protocol
   - **E.** Taps
5. What must be totally integrated into the system development life cycle?
   - **A.** Irrelevant
   - **B.** Tape library
   - **C.** IP storage access
   - **D.** Configuration file
   - **E.** Risk management

What is front-end security and how does it differ from back-end security?

Chapter 54

Physical Security Essentials

William Stallings
Independent consultant

Platt[1] distinguishes three elements of information system (IS) security:

- *Logical security.* Protects computer-based data from software-based and communication-based threats.
- *Physical security.* Also called *infrastructure security.* Protects the information systems that house data and the people who use, operate, and maintain the systems. Physical security must also prevent any type of physical access or intrusion that can compromise logical security.
- *Premises security.* Also known as *corporate or facilities security.* Protects the people and property within an entire area, facility, or building(s) and is usually required by laws, regulations, and fiduciary obligations. Premises security provides perimeter security, access control, smoke and fire detection, fire suppression, some environmental protection, and usually surveillance systems, alarms, and guards.

This chapter is concerned with physical security and with some overlapping areas of premises security. We begin by looking at physical security threats and then consider physical security prevention measures.

1. OVERVIEW

For information systems, the role of physical security is to protect the physical assets that support the storage and processing of information. Physical security involves two complementary requirements. First, physical security must prevent damage to the physical infrastructure that sustains the information system. In broad terms, that infrastructure includes the following:

- *Information system hardware.* Including data processing and storage equipment, transmission and networking facilities, and offline storage media. We can include in this category supporting documentation.
- *Physical facility.* The buildings and other structures housing the system and network components.
- *Supporting facilities.* These facilities underpin the operation of the information system. This category includes electrical power, communication services, and environmental controls (heat, humidity, etc.).
- *Personnel.* Humans involved in the control, maintenance, and use of the information systems.

Second, physical security must prevent misuse of the physical infrastructure that leads to the misuse or damage of the protected information. The misuse of the physical infrastructure can be accidental or malicious. It includes vandalism, theft of equipment, theft by copying, theft of services, and unauthorized entry.

Figure 54.1, based on Bosworth and Kabay[2] , suggests the overall context in which physical security concerns arise. The central concern is the information assets of an organization. These information assets provide value to the organization that possesses them, as indicated by the upper four items in Figure 54.1. In turn, the physical infrastructure is essential to providing for the storage and processing of these assets. The lower four items in Figure 54.1 are the concern of physical security. Not shown is the role of logical security, which consists of software- and protocol-based measures for ensuring data integrity, confidentiality, and so forth.

The role of physical security is affected by the operating location of the information system, which can be characterized as static, mobile, or portable. Our concern in this chapter is primarily with static systems, which are installed at fixed locations. A mobile system is installed in a vehicle, which serves the function of a structure for the system. Portable systems have no single installation point but may operate in a variety of locations, including buildings, vehicles, or in the open. The nature of the

system's installation determines the nature and severity of the threats of various types, including fire, roof leaks, unauthorized access, and so forth.

2. PHYSICAL SECURITY THREATS

In this pat of the chapter, we first look at the types of physical situations and occurrences that can constitute a threat to information systems. There are a number of ways in which such threats can be categorized. It is important to understand the spectrum of threats to information systems so that responsible administrators can ensure that prevention measures are comprehensive. We organize the threats into the following categories:

- Environmental threats
- Technical threats
- Human-caused threats

We begin with a discussion of natural disasters, which are a prime, but not the only, source of environmental threats. Then we look specifically at environmental threats, followed by technical and human-caused threats.

Natural Disasters

Natural disasters are the source of a wide range of environmental threats to datacenters, other information processing facilities, and their personnel. It is possible to assess the risk of various types of natural disasters and take suitable precautions so that catastrophic loss from natural disaster is prevented.

Table 54.1 lists six categories of natural disasters, the typical warning time for each event, whether or not personnel evacuation is indicated or possible, and the typical duration of each event. We comment briefly on the potential consequences of each type of disaster.

A tornado can generate winds that exceed hurricane strength in a narrow band along the tornado's path. There is substantial potential for structural damage, roof damage, and loss of outside equipment. There may be damage from wind and flying debris. Off site, a tornado may cause a temporary loss of local utility and communications. Offsite damage is typically followed by quick restoration of services. Tornado damage severity is measured by the Fujita Tornado Scale (see Table 54.2).

Hurricanes, tropical storms, and typhoons, collectively know as tropical cyclones, are among the most devastating naturally occurring hazards. Depending on strength, cyclones may also cause significant structural damage and damage to outside equipment at a particular site. Off site, there is the potential for severe regionwide damage to public infrastructure, utilities, and communications. If on-site operation must continue, then emergency supplies for personnel as well as a backup generator are needed. Further, the responsible site manager may need to mobilize private poststorm security measures, such as armed guards.

Table 54.3 summarizes the widely used Saffir/Simpson Hurricane Scale. In general, damage rises by about a factor of four for every category increase.

A major earthquake has the potential for the greatest damage and occurs without warning. A facility near the epicenter may suffer catastrophic, even complete, destruction, with significant and long-lasting damage to

TABLE 54.2 Fujita Tornado Intensity Scale.

Category	Wind Speed Range	Description of Damage
F0	40–72 mph 64–116 km/hr	Light damage. Some damage to chimneys; tree branches broken off; shallow-rooted trees pushed over; sign boards damaged.
F1	73–112 mph 117–180 km/hr	Moderate damage. The lower limit is the beginning of hurricane wind speed; roof surfaces peeled off; mobile homes pushed off foundations or overturned; moving autos pushed off the roads.
F2	113–157 mph 181–252 km/hr	Considerable damage. roofs torn off houses; mobile homes demolished; boxcars pushed over; large trees snapped or uprooted; light-object missiles generated.
F3	158–206 mph 253–332 km/hr	Severe damage. Roofs and some walls torn off well-constructed houses; trains overturned; most trees in forest uprooted; heavy cars lifted off ground and thrown.
F4	207–260 mph 333–418 km/hr	Devastating damage. Well-constructed houses leveled; structure with weak foundation blown off some distance; cars thrown and large missiles generated.
F5	261–318 mph 419–512 km/hr	Incredible damage. Strong frame houses lifted off foundations and carried considerable distance to disintegrate; automobile-sized missiles fly through the air in excess of 100 yards; trees debarked.

TABLE 54.3 Saffir/Simpson Hurricane Scale.

Category	Wind Speed Range	Storm Surge	Potential Damage
1	74–95 mph 119–153 km/hr	4–5 ft 1–2 m	Minimal
2	96–110 mph 154–177 km/hr	6–8 ft 2–3 m	Moderate
3	111–130 mph 178–209 km/hr	9–12 ft 3–4 m	Extensive
4	131–155 mph 210–249 km/hr	13–18 ft 4–5 m	Extreme
5	155 mph >249 km/hr	>18 ft >5 m	Catastrophic

datacenters and other IS facilities. Examples of inside damage include the toppling of unbraced computer hardware and site infrastructure equipment, including the collapse of raised floors. Personnel are at risk from broken glass and other flying debris. Off site, near the epicenter of a major earthquake, the damage equals and often exceeds that of a major hurricane. Structures that can withstand a hurricane, such as roads and bridges, may be damaged or destroyed, preventing the movement of fuel and other supplies.

An ice storm or blizzard can cause some disruption of or damage to IS facilities if outside equipment and the building are not designed to survive severe ice and snow accumulation. Off site, there may be widespread disruption of utilities and communications and roads may be dangerous or impassable.

The consequences of lightning strikes can range from no impact to disaster. The effects depend on the proximity of the strike and the efficacy of grounding and surge protector measures in place. Off site, there can be disruption of electrical power and there is the potential for fires.

Flooding is a concern in areas that are subject to flooding and for facilities that are in severe flood areas at low elevation. Damage can be severe, with long-lasting effects and the need for a major cleanup operation.

Environmental Threats

This category encompasses conditions in the environment that can damage or interrupt the service of information systems and the data they house. Off site, there may be severe regionwide damage to the public infrastructure and, in the case of severe hurricanes, it may take days, weeks, or even years to recover from the event.

Inappropriate Temperature and Humidity

Computers and related equipment are designed to operate within a certain temperature range. Most computer systems should be kept between 10 and 32 degrees Celsius (50 and 90 degrees Fahrenheit). Outside this range, resources might continue to operate but produce undesirable results. If the ambient temperature around a computer gets too high, the computer cannot adequately cool itself, and internal components can be damaged. If the temperature gets too cold, the system can undergo thermal shock when it is turned on, causing circuit boards or integrated circuits to crack.

Another temperature-related concern is the internal temperature of equipment, which can be significantly higher than room temperature. Computer-related equipment comes with its own temperature dissipation and cooling mechanisms, but these may rely on, or be affected by, external conditions. Such conditions include excessive ambient temperature, interruption of supply of power or heating, ventilation, and air-conditioning (HVAC) services, and vent blockage.

High humidity also poses a threat to electrical and electronic equipment. Long-term exposure to high humidity can result in corrosion. Condensation can threaten magnetic and optical storage media. Condensation can also cause a short circuit, which in turn can damage circuit boards. High humidity can also cause a galvanic effect that results in electroplating, in which metal from one connector slowly migrates to the mating connector, bonding the two together.

Very low humidity can also be a concern. Under prolonged conditions of low humidity, some materials may change shape and performance may be affected. Static electricity also becomes a concern. A person or object that becomes statically charged can damage electronic equipment by an electric discharge. Static electricity discharges as low as 10 volts can damage particularly sensitive electronic circuits, and discharges in the hundreds of volts can create significant damage to a variety of electronic circuits. Discharges from humans can reach into the thousands of volts, so this is a nontrivial threat. In general, relative humidity should be maintained between 40% and 60% to avoid the threats from both low and high humidity.

Fire and Smoke

Perhaps the most frightening physical threat is fire. It is a threat to human life and property. The threat is not only from the direct flame but also from heat, release of toxic fumes, water damage from fire suppression, and smoke damage. Further, fire can disrupt utilities, especially electricity.

The temperature due to fire increases with time, and in a typical building, fire effects follow the curve shown in Figure 54.2. The scale on the right side of Figure 54.2 shows the temperature at which various items melt or are damaged and therefore indicates how long after the fire is started such damage occurs.

Smoke damage related to fires can also be extensive. Smoke is an abrasive. It collects on the heads of unsealed magnetic disks, optical disks, and tape drives. Electrical fires can produce an acrid smoke that may damage other equipment and may be poisonous or carcinogenic.

The most common fire threat is from fires that originate within a facility, and, as discussed subsequently, there are a number of preventive and mitigating measures that can be taken. A more uncontrollable threat is faced from wildfires, which are a plausible concern in the western United States, portions of Australia (where the term *bushfire* is used), and a number of other countries.

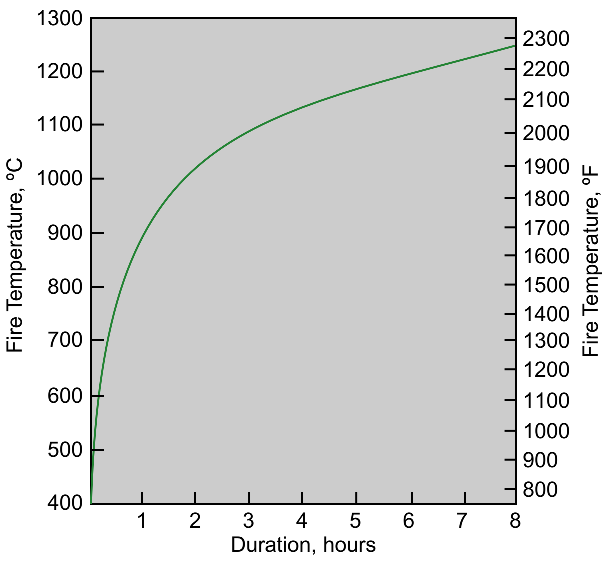

FIGURE 54.2 Fire effects.

Water Damage

Water and other stored liquids in proximity to computer equipment pose an obvious threat. The primary danger is an electrical short, which can happen if water bridges between a circuit board trace carrying voltage and a trace carrying ground. Moving water, such as in plumbing, and weather-created water from rain, snow, and ice also pose threats. A pipe may burst from a fault in the line or from freezing. Sprinkler systems, despite their security function, are a major threat to computer equipment and paper and electronic storage media. The system may be set off by a faulty temperature sensor, or a burst pipe may cause water to enter the computer room. For a large computer installation, an effort should be made to avoid any sources of water from one or two floors above. An example of a hazard from this direction is an overflowing toilet.

Less common but more catastrophic is floodwater. Much of the damage comes from the suspended material in the water. Floodwater leaves a muddy residue that is extraordinarily difficult to clean up.

Chemical, Radiological, and Biological Hazards

Chemical, radiological, and biological hazards pose a growing threat, both from intentional attack and from accidental discharge. None of these hazardous agents should be present in an information system environment, but either accidental or intentional intrusion is possible. Nearby discharges (from an overturned truck carrying hazardous materials) can be introduced through the ventilation system or open windows and, in the case of radiation, through perimeter walls. In addition, discharges in the vicinity can disrupt work by causing evacuations to be ordered. Flooding can also introduce biological or chemical contaminants.

In general, the primary risk of these hazards is to personnel. Radiation and chemical agents can also cause damage to electronic equipment.

Dust

Dust is a prevalent concern that is often overlooked. Even fibers from fabric and paper are abrasive and mildly conductive, although generally equipment is resistant to such contaminants. Larger influxes of dust can result from a number of incidents, such as a controlled explosion of a nearby building and a windstorm carrying debris from a wildfire. A more likely source of influx comes from dust surges that originate within the building due to construction or maintenance work.

Equipment with moving parts, such as rotating storage media and computer fans, are the most vulnerable to damage from dust. Dust can also block ventilation and reduce radiational cooling.

Infestation

One of the less pleasant physical threats is infestation, which covers a broad range of living organisms, including mold, insects, and rodents. High-humidity conditions can lead to the growth of mold and mildew, which can be harmful to both personnel and equipment. Insects, particularly those that attack wood and paper, are also a common threat.

Technical Threats

This category encompasses threats related to electrical power and electromagnetic emission.

Electrical Power

Electrical power is essential to the operation of an information system. All the electrical and electronic devices in the system require power, and most require uninterrupted utility power. Power utility problems can be broadly grouped into three categories: undervoltage, overvoltage, and noise.

An *undervoltage* occurs when the IS equipment receives less voltage than is required for normal operation. Undervoltage events range from temporary dips in the voltage supply to brownouts (prolonged undervoltage) and power outages. Most computers are designed to withstand prolonged voltage reductions of about 20% without shutting down and without operational error. Deeper dips or blackouts lasting more than a few milliseconds trigger a system shutdown. Generally, no damage is done, but service is interrupted.

Far more serious is an *overvoltage*. A surge of voltage can be caused by a utility company supply anomaly, by some internal (to the building) wiring fault, or by lightning. Damage is a function of intensity and duration and the effectiveness of any surge protectors between your equipment and the source of the surge. A sufficient surge can destroy silicon-based components, including processors and memories.

Power lines can also be a conduit for *noise*. In many cases, these spurious signals can endure through the filtering circuitry of the power supply and interfere with signals inside electronic devices, causing logical errors.

Electromagnetic Interference

Noise along a power supply line is only one source of electromagnetic interference (EMI). Motors, fans, heavy equipment, and even other computers generate electrical noise that can cause intermittent problems with the computer you are using. This noise can be transmitted through space as well as nearby power lines.

Another source of EMI is high-intensity emissions from nearby commercial radio stations and microwave relay antennas. Even low-intensity devices, such as cellular telephones, can interfere with sensitive electronic equipment.

Human-Caused Physical Threats

Human-caused threats are more difficult to deal with than the environmental and technical threats discussed so far. Human-caused threats are less predictable than other types of physical threats. Worse, human-caused threats are specifically designed to overcome prevention measures and/or seek the most vulnerable point of attack. We can group such threats into the following categories:

- *Unauthorized physical access.* Those who are not employees should not be in the building or building complex at all unless accompanied by an authorized individual. Not counting PCs and workstations, information system assets, such as servers, mainframe computers, network equipment, and storage networks, are generally housed in restricted areas. Access to such areas is usually restricted to only a certain number of employees. Unauthorized physical access can lead to other threats, such as theft, vandalism, or misuse.
- *Theft.* This threat includes theft of equipment and theft of data by copying. Eavesdropping and wiretapping also fall into this category. Theft can be at the hands of an outsider who has gained unauthorized access or by an insider.
- *Vandalism.* This threat includes destruction of equipment and destruction of data.
- *Misuse.* This category includes improper use of resources by those who are authorized to use them, as well as use of resources by individuals not authorized to use the resources at all.

3. PHYSICAL SECURITY PREVENTION AND MITIGATION MEASURES

In this part of the chapter, we look at a range of techniques for preventing, or in some cases simply deterring, physical attacks. We begin with a survey of some of the techniques for dealing with environmental and technical threats and then move on to human-caused threats.

Environmental Threats

We discuss these threats in the same order.

Inappropriate Temperature and Humidity

Dealing with this problem is primarily a matter of having environmental-control equipment of appropriate capacity and appropriate sensors to warn of thresholds being exceeded. Beyond that, the principal requirement is the maintenance of a power supply, discussed subsequently.

Fire and Smoke

Dealing with fire involves a combination of alarms, preventive measures, and fire mitigation. Martin provides the following list of necessary measures[3] :

- Choice of site to minimize likelihood of disaster. Few disastrous fires originate in a well-protected computer room or IS facility. The IS area should be chosen to minimize fire, water, and smoke hazards from adjoining areas. Common walls with other activities should have at least a one-hour fire-protection rating.
- Air conditioning and other ducts designed so as not to spread fire. There are standard guidelines and specifications for such designs.
- Positioning of equipment to minimize damage.
- Good housekeeping. Records and flammables must not be stored in the IS area. Tidy installation of IS equipment is crucial.
- Hand-operated fire extinguishers readily available, clearly marked, and regularly tested.
- Automatic fire extinguishers installed. Installation should be such that the extinguishers are unlikely to cause damage to equipment or danger to personnel.
- Fire detectors. The detectors sound alarms inside the IS room and with external authorities, and start

3. J. Martin, *Security, Accuracy, and Privacy in Computer Systems,* Prentice Hall, 1973.

automatic fire extinguishers after a delay to permit human intervention.
- Equipment power-off switch. This switch must be clearly marked and unobstructed. All personnel must be familiar with power-off procedures.
- Emergency procedures posted.
- Personnel safety. Safety must be considered in designing the building layout and emergency procedures.
- Important records stored in fireproof cabinets or vaults.
- Records needed for file reconstruction stored off the premises.
- Up-to-date duplicate of all programs stored off the premises.
- Contingency plan for use of equipment elsewhere should the computers be destroyed.
- Insurance company and local fire department should inspect the facility.

To deal with the threat of smoke, the responsible manager should install smoke detectors in every room that contains computer equipment as well as under raised floors and over suspended ceilings. Smoking should not be permitted in computer rooms.

For wildfires, the available countermeasures are limited. Fire-resistant building techniques are costly and difficult to justify.

Water Damage

Prevention and mitigation measures for water threats must encompass the range of such threats. For plumbing leaks, the cost of relocating threatening lines is generally difficult to justify. With knowledge of the exact layout of water supply lines, measures can be taken to locate equipment sensibly. The location of all shutoff valves should be clearly visible or at least clearly documented, and responsible personnel should know the procedures to follow in case of emergency.

To deal with both plumbing leaks and other sources of water, sensors are vital. Water sensors should be located on the floor of computer rooms as well as under raised floors and should cut off power automatically in the event of a flood.

Other Environmental Threats

For chemical, biological, and radiological threats, specific technical approaches are available, including infrastructure design, sensor design and placement, mitigation procedures, personnel training, and so forth. Standards and techniques in these areas continue to evolve.

As for dust hazards, the obvious prevention method is to limit dust through the use and proper filter maintenance and regular IS room maintenance. For infestations, regular pest control procedures may be needed, starting with maintaining a clean environment.

Technical Threats

To deal with brief power interruptions, an uninterruptible power supply (UPS) should be employed for each piece of critical equipment. The UPS is a battery backup unit that can maintain power to processors, monitors, and other equipment for a period of minutes. UPS units can also function as surge protectors, power noise filters, and automatic shutdown devices when the battery runs low.

For longer blackouts or brownouts, critical equipment should be connected to an emergency power source, such as a generator. For reliable service, a range of issues need to be addressed by management, including product selection, generator placement, personnel training, testing and maintenance schedules, and so forth.

To deal with electromagnetic interference, a combination of filters and shielding can be used. The specific technical details will depend on the infrastructure design and the anticipated sources and nature of the interference.

Human-Caused Physical Threats

The general approach to human-caused physical threats is physical access control. Based on Michael,[4] we can suggest a spectrum of approaches that can be used to restrict access to equipment. These methods can be used in combination:

- Physical contact with a resource is restricted by restricting access to the building in which the resource is housed. This approach is intended to deny access to outsiders but does not address the issue of unauthorized insiders or employees.
- Physical contact with a resource is restricted by putting the resource in a locked cabinet, safe, or room.
- A machine may be accessed, but it is secured (perhaps permanently bolted) to an object that is difficult to move. This will deter theft but not vandalism, unauthorized access, or misuse.
- A security device controls the power switch.
- A movable resource is equipped with a tracking device so that a sensing portal can alert security personnel or trigger an automated barrier to prevent the object from being moved out of its proper security area.
- A portable object is equipped with a tracking device so that its current position can be monitored continually.

4. M. Michael, "Physical security measures," In H. Bidgoli, (ed.), *Handbook of Information Security,* Wiley, 2006.

The first two of the preceding approaches isolate the equipment. Techniques that can be used for this type of access control include controlled areas patrolled or guarded by personnel, barriers that isolate each area, entry points in the barrier (doors), and locks or screening measures at each entry point. Physical access control should address not just computers and other IS equipment but also locations of wiring used to connect systems, the electrical power service, the HVAC equipment and distribution system, telephone and communications lines, backup media, and documents.

In addition to physical and procedural barriers, an effective physical access control regime includes a variety of sensors and alarms to detect intruders and unauthorized access or movement of equipment. Surveillance systems are frequently an integral part of building security, and special-purpose surveillance systems for the IS area are generally also warranted. Such systems should provide real-time remote viewing as well as recording.

4. RECOVERY FROM PHYSICAL SECURITY BREACHES

The most essential element of recovery from physical security breaches is redundancy. Redundancy does not undo any breaches of confidentiality, such as the theft of data or documents, but it does provide for recovery from loss of data. Ideally, all the important data in the system should be available off site and updated as near to real time as is warranted based on a cost/benefit tradeoff. With broadband connections now almost universally available, batch encrypted backups over private networks or the Internet are warranted and can be carried out on whatever schedule is deemed appropriate by management. At the extreme, a *hotsite* can be created off site that is ready to take over operation instantly and has available to it a near-real-time copy of operational data.

Recovery from physical damage to the equipment or the site depends on the nature of the damage and, importantly, the nature of the residue. Water, smoke, and fire damage may leave behind hazardous materials that must be meticulously removed from the site before normal operations and the normal equipment suite can be reconstituted. In many cases, this requires bringing in disaster recovery specialists from outside the organization to do the cleanup.

5. THREAT ASSESSMENT, PLANNING, AND PLAN IMPLEMENTATION

We have surveyed a number of threats to physical security and a number of approaches to prevention, mitigation, and recovery. To implement a physical security program, an organization must conduct a threat assessment to determine the amount of resources to devote to physical security and the allocation of those resources against the various threats. This process also applies to logical security.

Threat Assessment

In this part of the chapter, we follow Platt[5] in outlining a typical sequence of steps that an organization should take:

1. *Set up a steering committee.* The threat assessment should not be left only to a security officer or to IS management. All those who have a stake in the security of the IS assets, including all of the user communities, should be brought into the process.
2. *Obtain information and assistance.* Historical information concerning external threats, such as flood and fire is the best starting point. This information can often be obtained from government agencies and weather bureaus. In the United States, the Federal Emergency Management Agency (FEMA) can provide much useful information. FEMA has a number of publications available online that provide specific guidance in a wide variety of physical security areas (www.fema.gov/business/index.shtm). The committee should also seek expert advice from vendors, suppliers, neighboring businesses, service and maintenance personnel, consultants, and academics.
3. *Identify all possible threats.* List all possible threats, including those that are specific to IS operations as well as those that are more general, covering the building and the geographic area.
4. *Determine the likelihood of each threat.* This is clearly a difficult task. One approach is to use a scale of 1 (least likely) to 5 (most likely) so that threats can be grouped to suggest where attention should be directed. All the information from Step 2 can be applied to this task.
5. *Approximate the direct costs.* For each threat, the committee must estimate not only the threat's likelihood but also its severity in terms of consequences. Again a relative scale of 1 (low) to 5 (high) in terms of costs and losses is a reasonable approach. For both Steps 4 and 5, an attempt to use a finer-grained scale, or to assign specific probabilities and specific costs, is likely to produce the impression of greater precision and knowledge about future threats than is possible.
6. *Consider cascading costs.* Some threats can trigger consequential threats that add still more impact costs. For example, a fire can cause direct flame, heat, and

5. F. Platt, "Physical threats to the information infrastructure," in S. Bosworth, and M. Kabay, (eds.), *Computer Security Handbook,* Wiley, 2002.

smoke damage as well as disrupt utilities and result in water damage.

7. *Prioritize the threats.* The goal here is to determine the relative importance of the threats as a guide to focusing resources on prevention. A simple formula yields a prioritized list:

$$\text{Importance} = \text{Likelihood} \times [\text{Direct Cost} + \text{Secondary Cost}]$$

where the scale values (1 through 5) are used in the formula.

8. *Complete the threat assessment report.* The committee can now prepare a report that includes the prioritized list, with commentary on how the results were achieved. This report serves as the reference source for the planning process that follows.

Planning and Implementation

Once a threat assessment has been done, the steering committee, or another committee, can develop a plan for threat prevention, mitigation, and recovery. The following is a typical sequence of steps an organization could take:

1. *Assess internal and external resources.* These include resources for prevention as well as response. A reasonable approach is again to use a relative scale from 1 (strong ability to prevent and respond) to 5 (weak ability to prevent and respond). This scale can be combined with the threat priority score to focus resource planning.
2. *Identify challenges and prioritize activities.* Determine specific goals and milestones. Make a list of tasks to be performed, by whom and when. Determine how you will address the problem areas and resource shortfalls that were identified in the vulnerability analysis.
3. *Develop a plan.* The plan should include prevention measures and equipment needed and emergency response procedures. The plan should include support documents, such as emergency call lists, building and site maps, and resource lists.
4. *Implement the plan.* Implementation includes acquiring new equipment, assigning responsibilities, conducting training, monitoring plan implementation, and updating the plan regularly.

6. EXAMPLE: A CORPORATE PHYSICAL SECURITY POLICY

To give the reader a feel for how organizations deal with physical security, we provide a real-world example of a physical security policy. The company is a European Union (EU)-based engineering consulting firm that specializes in the provision of planning, design, and management services for infrastructure development worldwide. With interests in transportation, water, maritime, and property, the company is undertaking commissions in over 70 countries from a network of more than 70 offices.

Figure 54.3 is extracted from the company's security standards document. For our purposes, we have changed the name of the company to *Company* wherever it appears in the document. The company's physical security policy relies heavily on ISO 17799 *(Code of Practice for Information Security Management).*

7. INTEGRATION OF PHYSICAL AND LOGICAL SECURITY

Physical security involves numerous detection devices, such as sensors and alarms, and numerous prevention devices and measures, such as locks and physical barriers. It should be clear that there is much scope for automation and for the integration of various computerized and electronic devices. Clearly, physical security can be made more effective if there is a central destination for all alerts and alarms and if there is central control of all automated access control mechanisms, such as smart card entry sites.

From the point of view of both effectiveness and cost, there is increasing interest not only in integrating automated physical security functions but in integrating, to the extent possible, automated physical security and logical security functions. The most promising area is that of access control. Examples of ways to integrate physical and logical access control include the following:

- Use of a single ID card for physical and logical access. This can be a simple magnetic-strip card or a smart card.
- Single-step user/card enrollment and termination across all identity and access control databases.
- A central ID-management system instead of multiple disparate user directories and databases.
- Unified event monitoring and correlation.

As an example of the utility of this integration, suppose that an alert indicates that Bob has logged on to the company's wireless network (an event generated by the logical access control system) but did not enter the building (an event generated from the physical access control system). Combined, these two events suggest that someone is hijacking Bob's wireless account.

For the integration of physical and logical access control to be practical, a wide range of vendors must conform to standards that cover smart card protocols, authentication and access control formats and protocols, database entries, message formats, and so on. An important step in this direction is FIPS 201-2 *(Personal Identity Verification (PIV) of Federal Employees and Contractors),* issued in 2011. The standard defines a reliable, governmentwide PIV system for use in applications

5. Physical and Environmental security

5.1. ***Secure Areas***

5.1.1. ***Physical Security Perimeter -*** Company shall use security perimeters to protect all non-public areas, commensurate with the value of the assets therein. Business critical information processing facilities located in unattended buildings shall also be alarmed to a permanently manned remote alarm monitoring station.

5.1.2. ***Physical Entry Controls -*** Secure areas shall be segregated and protected by appropriate entry controls to ensure that only authorised personnel are allowed access. Similar controls are also required where the building is shared with, or accessed by, non-Company staff and organisations not acting on behalf of Company.

5.1.3. ***Securing Offices, Rooms and Facilities -*** Secure areas shall be created in order to protect office, rooms and facilities with special security requirements.

5.1.4. ***Working in Secure Areas -*** Additional controls and guidelines for working in secure areas shall be used to enhance the security provided by the physical control protecting the secure areas.

Employees of Company should be aware that additional controls and guidelines for working in secure areas to enhance the security provided by the physical control protecting the secure areas might be in force. For further clarification they should contact their Line Manager.

5.1.5. ***Isolated Access Points -*** Isolated access points, additional to building main entrances (e.g. Delivery and Loading areas) shall be controlled and, if possible, isolated from secure areas to avoid unauthorised access.

5.1.6. ***Sign Posting Of Computer Installations -*** Business critical computer installations sited within a building must not be identified by the use of descriptive sign posts or other displays. Where such sign posts or other displays are used they must be worded in such a way so as not to highlight the business critical nature of the activity taking place within the building.

5.2. ***Equipment Security***

5.2.1. ***Equipment Sitting and Protection -*** Equipment shall be sited or protected to reduce the risk from environmental threats and hazards, and opportunity for unauthorised access.

5.2.2. ***Power Supply -*** The equipment shall be protected from power failure and other electrical anomalies.

5.2.3. ***Cabling Security -*** Power and telecommunication cabling carrying data or supporting information services shall be protected from interception or damage commensurate with the business criticality of the operations they serve.

5.2.4. ***Equipment Maintenance -*** Equipment shall be maintained in accordance with manufacturer's instruction and/or documented procedures to ensure its continued availability and integrity.

5.2.5. ***Security of Equipment off-premises -*** Security procedures and controls shall be used to secure equipment used outside any Company's premises

Employees are to note that there should be security procedures and controls to secure equipment used outside any Company premises. Advice on these procedures can be sought from the Group Security Manager.

5.2.6. ***Secure Disposal or Re-use of Equipment -*** Information shall be erased from equipment prior to disposal or reuse.

For further guidance contact the Group Security Manager.

5.2.7. ***Security of the Access Network -*** Company shall implement access control measures, determined by a risk assessment, to ensure that only authorised people have access to the Access Network (including: cabinets, cabling, nodes etc.).

FIGURE 54.3 The Company's physical security policy.

5.2.8. ***Security of PCs -*** Every Company owned PC must have an owner who is responsible for its general management and control. Users of PCs are personally responsible for the physical and logical security of any PC they use. Users of Company PCs are personally responsible for the physical and logical security of any PC they use, as defined within the Staff Handbook.

5.2.9. ***Removal of "Captured Data" -*** Where any device (software or hardware based) has been introduced to the network that captures data for analytical purposes, all data must be wiped off of this device prior to removal from the Company Site. The removal of this data from site for analysis can only be approved by the MIS Technology Manager.

5.3. ***General Controls***

5.3.1. ***Security Controls -*** Security Settings are to be utilised and configurations must be controlled

No security settings or software on Company systems are to be changed without authorisation from MIS Support

5.3.2. ***Clear Screen Policy -*** Company shall have and implement clear-screen policy in order to reduce the risks of unauthorised access, loss of, and damage to information.

This will be implemented when all Users of the Company system have Windows XP operating system.

When the User has the Windows XP system they are to carry out the following:

- *Select the Settings tab within the START area on the desktop screen.*
- *Select Control Panel.*
- *Select the icon called DISPLAY.*
- *Select the Screensaver Tab.*
- *Set a Screen saver.*
- *Set the time for 15 Mins.*
- *Tick the Password Protect box; remember this is the same password that you utilise to log on to the system.*

Staff are to lock their screens using the Ctrl-Alt-Del when they leave their desk

5.3.3. ***Clear Desk Policy –*** Staff shall ensure that they operate a Clear Desk Policy

Each member of staff is asked to take personal and active responsibility for maintaining a "clear desk" policy whereby files and papers are filed or otherwise cleared away before leaving the office at the end of each day

5.3.4. ***Removal of Property -*** Equipment, information or software belonging to the organisation shall not be removed without authorisation.

Equipment, information or software belonging to Company shall not be removed without authorisation from the Project Manager or Line Manager and the MIS Support.

5.3.5. ***People Identification -*** All Company staff must have visible the appropriate identification whenever they are in Company premises.

5.3.6. ***Visitors -*** All Company premises will have a process for dealing with visitors. All Visitors must be sponsored and wear the appropriate identification whenever they are in Company premises.

5.3.7. ***Legal Right of Entry -*** Entry must be permitted to official bodies when entry is demanded on production of a court order or when the person has other legal rights. Advice must be sought from management or the Group Security Manager as a matter of urgency.

FIGURE 54.3 (Continued)

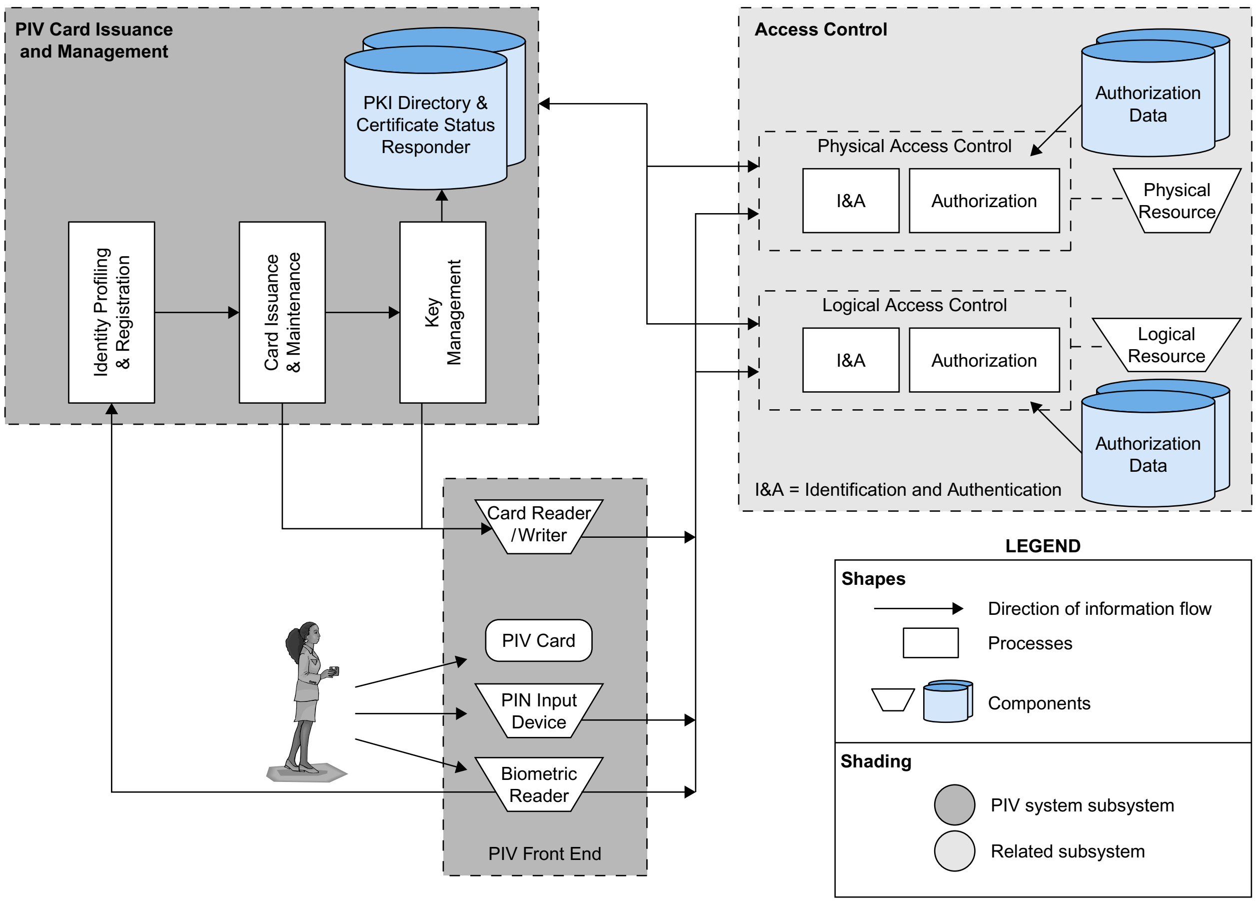

FIGURE 54.4 FIPS 201 PIV system model.

such as access to federally controlled facilities and information systems. The standard specifies a PIV system within which common identification credentials can be created and later used to verify a claimed identity. The standard also identifies federal governmentwide requirements for security levels that are dependent on risks to the facility or information being protected. The standard applies to private-sector contractors as well, and serves as a useful guideline for any organization.

Figure 54.4 illustrates the major components of FIPS 201-2 compliant systems. The PIV front end defines the physical interface to a user who is requesting access to a facility, which could be either physical access to a protected physical area or logical access to an information system. The PIV front-end subsystem supports up to three-factor authentication; the number of factors used depends on the level of security required. The front end makes use of a smart card, known as a *PIV card,* which is a dual-interface contact and contactless card. The card holds a cardholder photograph, X.509 certificates, cryptographic keys, biometric data, and the cardholder unique identifier (CHUID). Certain cardholder information may be read-protected and require a personal identification number (PIN) for read access by the card reader. The biometric reader, in the current version of the standard, is a fingerprint reader.

The standard defines three assurance levels for verification of the card and the encoded data stored on the card, which in turn leads to verifying the authenticity of the person holding the credential. A level of *some confidence* corresponds to use of the card reader and PIN. A level of *high confidence* adds a biometric comparison of a fingerprint captured and encoded on the card during the card-issuing process and a fingerprint scanned at the physical access point. A *very high confidence* level requires that the process just described is completed at a control point attended by an official observer.

The other major component of the PIV system is the *PIV card issuance and management subsystem.* This subsystem includes the components responsible for identity proofing and registration, card and key issuance and management, and the various repositories and services (public key infrastructure [PKI] directory, certificate status servers) required as part of the verification infrastructure.

The PIV system interacts with an *access control subsystem,* which includes components responsible for

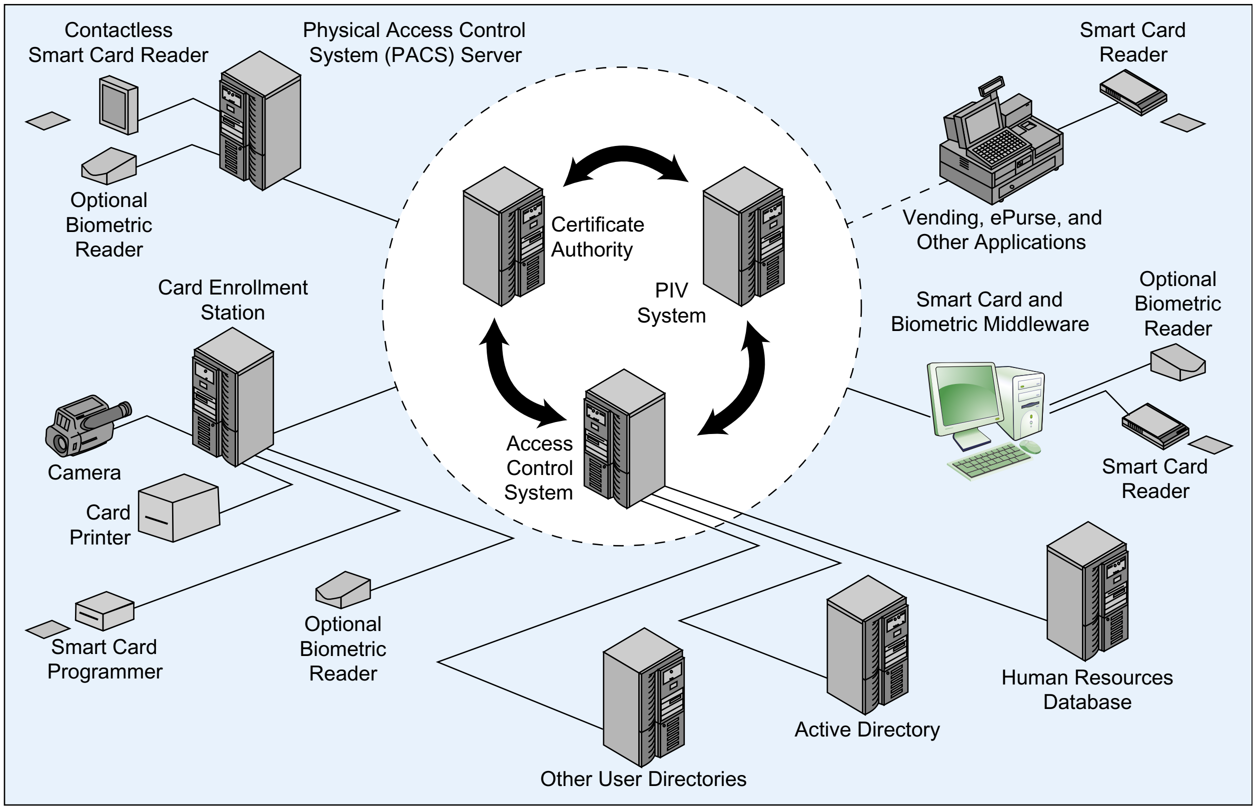

FIGURE 54.5 Convergence example (based on [FORR06]).

determining a particular PIV cardholder's access to a physical or logical resource. FIPS 201-1 standardizes data formats and protocols for interaction between the PIV system and the access control system.

Unlike the typical card number/facility code encoded on most access control cards, the FIPS 201 CHUID takes authentication to a new level, through the use of an expiration date (a required CHUID data field) and an optional CHUID digital signature. A digital signature can be checked to ensure that the CHUID recorded on the card was digitally signed by a trusted source and that the CHUID data have not been altered since the card was signed. The CHUID expiration date can be checked to verify that the card has not expired. This is independent of whatever expiration date is associated with cardholder privileges. Reading and verifying the CHUID alone provides only some assurance of identity because it authenticates the card data, not the cardholder. The PIN and biometric factors provide identity verification of the individual.

Figure 54.5, adapted from Forristal,[6] illustrates the convergence of physical and logical access control using FIPS 201-2. The core of the system includes the PIV and access control system as well as a certificate authority for signing CHUIDs. The other elements of Figure 54.5 provide examples of the use of the system core for integrating physical and logical access control.

If the integration of physical and logical access control extends beyond a unified front end to an integration of system elements, a number of benefits accrue, including the following[7] :

- Employees gain a single, unified access control authentication device; this cuts down on misplaced tokens, reduces training and overhead, and allows seamless access.
- A single logical location for employee ID management reduces duplicate data entry operations and allows for immediate and real-time authorization revocation of all enterprise resources.
- Auditing and forensic groups have a central repository for access control investigations.
- Hardware unification can reduce the number of vendor purchase-and-support contracts.
- Certificate-based access control systems can leverage user ID certificates for other security applications, such as document esigning and data encryption.

7. J. Forristal, "Physical/logical convergence," *Network Computing*, November 23, 2006.

An Agenda for Action for Physical Security

The brevity of a checklist can be helpful, but it in no way makes up for the detail of the text. Thus, the following set of Check Points for Physical Security must be adhered to (check all tasks completed):

Create a Secure Environment: Building and Room Construction:

_____**1.** Does each secure room or facility have low visibility (no unnecessary signs)?
_____**2.** Has the room or facility been constructed with full-height walls?
_____**3.** Has the room or facility been constructed with a fireproof ceiling?
_____**4.** Are there two or fewer doorways?
_____**5.** Are doors solid and fireproof?
_____**6.** Are doors equipped with locks?
_____**7.** Are window openings to secure areas kept as small as possible?
_____**8.** Are windows equipped with locks?
_____**9.** Are keys and combinations to door and window locks secured responsibly?
_____**10.** Have alternatives to traditional lock and key security measures (bars, anti-theft cabling, magnetic key cards, and motion detectors) been considered?
_____**11.** Have both automatic and manual fire equipment been properly installed?
_____**12.** Are personnel properly trained for fire emergencies?
_____**13.** Are acceptable room temperatures always maintained (between 50 and 80 degrees Fahrenheit)?
_____**14.** Are acceptable humidity ranges always maintained (between 20 and 80 percent)?
_____**15.** Are eating, drinking, and smoking regulations in place and enforced?
_____**16.** Has all non-essential, potentially flammable, material (curtains and stacks of computer paper) been removed from secure areas?

Guard Equipment:

_____**17.** Has equipment been identified as critical or general use, and segregated appropriately?
_____**18.** Is equipment housed out of sight and reach from doors and windows, and away from radiators, heating vents, air conditioners, and other duct work?
_____**19.** Are plugs, cabling, and other wires protected from foot traffic?
_____**20.** Are up-to-date records of all equipment brand names, model names, and serial numbers kept in a secure location?
_____**21.** Have qualified technicians (staff or vendors) been identified to repair critical equipment if and when it fails?
_____**22.** Has contact information for repair technicians (telephone numbers, customer numbers, maintenance contract numbers) been stored in a secure but accessible place?
_____**23.** Are repair workers and outside technicians required to adhere to the organization's security policies concerning sensitive information?

Rebuff Theft:

_____**24.** Has all equipment been labeled in an overt way that clearly and permanently identifies its owner (the school name)?
_____**25.** Has all equipment been labeled in a covert way that only authorized staff would know to look for (inside the cover)?
_____**26.** Have steps been taken to make it difficult for unauthorized people to tamper with equipment (by replacing case screws with Allen-type screws)?
_____**27.** Have security staff been provided up-to-date lists of personnel and their respective access authority?
_____**28.** Are security staff required to verify identification of unknown people before permitting access to facilities?
_____**29.** Are security staff required to maintain a log of all equipment taken in and out of secure areas?

Attend to Portable Equipment and Computers:

_____**30.** Do users know not to leave laptops and other portable equipment unattended outside of the office?
_____**31.** Do users know and follow proper transportation and storage procedures for laptops and other portable equipment?

Regulate Power Supplies:

_____**32.** Are surge protectors used with all equipment?
_____**33.** Are Uninterruptible Power Supplies (UPSs) in place for critical systems?
_____**34.** Have power supplies been "insulated" from environmental threats by a professional electrician?
_____**35.** Has consideration been given to the use of electrical outlets so as to avoid overloading?
_____**36.** Are the negative effects of static electricity minimized through the use of anti-static carpeting, pads, and sprays as necessary?

Protect Output:

_____**37.** Are photocopiers, fax machines, and scanners kept in open view?
_____**38.** Are printers assigned to users with similar security clearances?
_____**39.** Is every printed copy of confidential information labeled as "confidential"?
_____**40.** Are outside delivery services required to adhere to security practices when transporting sensitive information?
_____**41.** Are all paper copies of sensitive information shredded before being discarded?

Finally, let's briefly look at a physical security checklist. The effectiveness of the recommendations in the physical security checklist is most useful when initiated as part of a larger plan to develop and implement security policy throughout an organization.

8. PHYSICAL SECURITY CHECKLIST

While it may be tempting to simply refer to the following checklist as your security plan, to do so would limit the effectiveness of the recommendations. Some recommendations and considerations are included the following checklist: "An Agenda For Action For Physical Security").

9. SUMMARY

Physical security requires that building site(s) be safeguarded in a way that minimizes the risk of resource theft and destruction. To accomplish this, decision-makers must be concerned about building construction, room assignments, emergency procedures, regulations governing equipment placement and use, power supplies, product handling, and relationships with outside contractors and agencies.

The physical plant must be satisfactorily secured to prevent those people who are not authorized to enter the site and use equipment from doing so. A building does not need to feel like a fort to be safe. Well-conceived plans to secure a building can be initiated without adding undue burden on your staff. After all, if they require access, they will receive it—as long as they were aware of, and abide by, the organization's stated security policies and guidelines. The only way to ensure this is to demand that before any person is given access to your system, they have first signed and returned a valid Security Agreement. This necessary security policy is too important to permit exceptions.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Information system hardware includes data processing and storage equipment, transmission and networking facilities, and online storage media.
2. True or False? Physical facility includes the buildings and other structures housing the system and network components.
3. True or False? Supporting facilities under scores the operation of the information system.
4. True or False? Personnel are humans involved in the control, maintenance, and use of the information systems.
5. True or False? It is possible to assess the risk of various types of natural disasters and take suitable precautions so that catastrophic loss from natural disaster is achieved.

Multiple Choice

1. What are the three elements of information system (IS) security?
   - **A.** Logical security
   - **B.** Physical security
   - **C.** Maritime security
   - **D.** Premises security
   - **E.** Wireless security
2. In broad terms, which of the following is not included in the critical infrastructure?
   - **A.** Environmental threats
   - **B.** Information system hardware
   - **C.** Physical facility
   - **D.** Supporting facilities
   - **E.** Personnel
3. Which of the following are threats?
   - **A.** Environmental
   - **B.** Natural
   - **C.** Technical
   - **D.** Access
   - **E.** Human-caused
4. Which of the following is not a human-caused threat?
   - **A.** Unauthorized physical access
   - **B.** Theft
   - **C.** Vandalism
   - **D.** Decryption
   - **E.** Misuse
5. Dealing with fire involves a combination of alarms, preventive measures, and fire mitigation. Which of the following is not a necessary measure?
   - **A.** Choice of site to minimize likelihood of disaster
   - **B.** Positioning of equipment to minimize damage
   - **C.** Good housekeeping
   - **D.** Fire detectors
   - **E.** Physical contact

EXERCISE

Problem

A company's physical security team analyzed physical security threats and vulnerabilities for their systems. What type of vulnerabilities did the company focus on?

Hands-On Projects

Project

An engineering company operating within a highly regulated industry, in which privacy and compliance are of paramount importance, wanted to compare itself relative to its peers in physical security provision and establish a baseline from which to quantify improvement. Please identify the best practices; compare organizational and outsourcing models; compare security technologies utilized; and, calibrate investment in physical security against its peers.

Case Projects

Problem

This case study illustrates how a company uses intelligent video processing (a sub-system of its video surveillance system) to detect intrusions at land ports of entry. Virtual fences are integrated into each facility to compliment both the facility's perimeter physical security system (composed of a combination of fences, gates, and barriers) and the video surveillance system. What should happen if these virtual fences are breached?

Optional Team Case Project

Problem

A company wants to further develop its access control system (ACS) use of video, proximity-based ID cards, biometrics, RFID, VoIP, and remotely controlled gates for manned and unmanned access control. What does the company need to do to further develop its ACS?

Chapter 55

Disaster Recovery

Scott R. Ellis and Lauren Collins
kCura Corporation

1. INTRODUCTION

In almost every organization, when a technology-oriented task is at hand, and where no one knows who would handle the request, it typically lands in the information technology department (IT). Whether the task consists of a special, faulty light bulb or a backup for a grease stop in the kitchen sink, organizations rely heavily on the IT department to know the unknown, and to fix anything that breaks.

Disaster recovery (DR), not unlike the plugged sink, is another task that many organizations fail to consider until after much of the technology groundwork has been laid, the corporation is profitable, and suddenly someone realizes that *not* having a DR site is a serious risk to the business. It is at this time that they begin to consider, and they begin to ponder, what a strategy might look like that enables the business to continue to run in the event of Force Majeure or some other disaster, such as if a hacker came in and tore their system down, or somehow seized control of it.

Hardware, physical or virtual, must be acquired and configured to capture the environment as it currently sits—and it must be able to continue with its synchronization. Whether this is by the minute, the hour, the day, or the week is a business decision. In fact, much of the DR strategy is driven by business continuity requirements. In the event of a disaster, there must be a plan in place that considers which individuals will act in the event of a disaster. Those individuals must know what constitutes a disaster, and the roles must be defined for those individuals.

2. MEASURING RISK AND AVOIDING DISASTER

A key component of a disaster recovery (DR) plan is for the committee to assess conceivable risks to the organization that could result in the disasters or emergency situations themselves. All events must be considered, and the impact must also be reflected upon so that the organization has the ability to continue and deliver business as usual. Quantitative and qualitative risks are considered separately in a DR plan; however, both come together when determining how an organizations reputation and earnings should be managed in the event of a disaster. Risk is assessed on an inherent and residual basis, allowing an entity to understand the extent to which potential events might impact objectives from two perspectives, likelihood and impact.

Assessing Risk in the Enterprise

Enterprise Risk Management (ERM) is not a template that can be given to every company to meet their needs and fit their business structure. Proper risk assessment identifies the risks throughout the organization and specifies the external and internal sources that the organization may face. The organization engages members from each organizational unit (Executives, HR, Finance, etc.), and asks questions such as "What do you perceive to be the largest risks to the company in terms of significance and likelihood?" and "What do you perceive to be the biggest risks within your control?" After a common understanding is met and all are aware of the risks, such risk assessments should be linked to strategic objectives as shown in Figure 55.1.

Once the company has an understanding of the top risks that can impact the organization, the executive team determines the company's risk appetite and risk tolerance. Risk appetite is the amount of risk, on a comprehensive level, that an entity is willing to accept in pursuit of value. Risk tolerance, on the other hand, is the range of acceptable variation around the company's objectives. The key is to determine the degree of maturity that meets the needs of your organization.

Steps in the Risk Process

There are five steps to consider for a company to come out ahead when a disaster hits to avoid risk and protect your data. The following checklist (see checklist: An

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00055-6

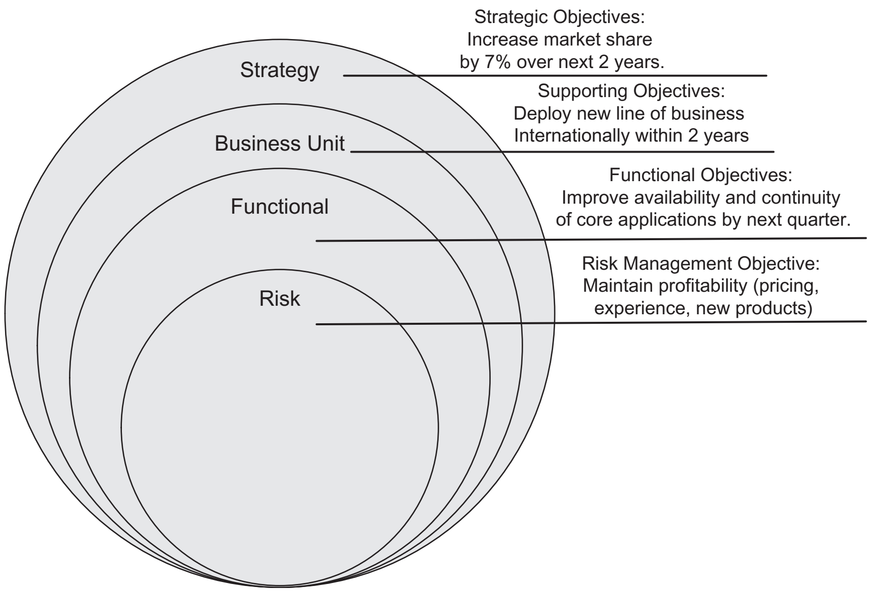

FIGURE 55.1 Risk assessments are linked to strategic objectives in an organization as a whole to allow a company to understand the risks in the organization, the company's risk appetite, and risk tolerance.

Agenda for Action for Risk Assessment) is a list of these steps, from assessment to planning, architecting, specifying and implementing a full-bodied disaster recovery (DR) solution.

Downtime presents serious consequences for businesses, no matter what their function may be. It is difficult, if not impossible, to recoup lost revenue and rebuild a corporate reputation that is damaged by an outage. While professionals cannot expect to avoid every downtime event, the majority of system downtime is caused by preventable failures. Distinguishing between planned and unplanned system downtime allocates

An Agenda for Action for Risk Assessment

Steps in Risk Assessment (check all tasks completed):

_____**1.** Discover the potential threats:

- _____**a.** Environmental (tornado, hurricane, flood, earthquake, fire, landslide, epidemic).
- _____**b.** Organized or deliberate disruption (terrorism, war, arson).
- _____**c.** Loss of utilities or services (electrical power failure, petroleum shortage, communications services breakdown).
- _____**d.** Equipment or system failure (internal power failure, air conditioning failure, production line failure, equipment failure).
- _____**e.** Security threat (leak of sensitive information, loss of records or data, cybercrime).
- _____**f.** Supplementary emergency situations (workplace violence, public transportation disruption, health and safety hazard).

_____**2.** Determine requirements:

- _____**a.** Prioritize processes
- _____**b.** Determine recovery objectives
- _____**c.** Plan for common incidents
- _____**d.** Communicate the plan
- _____**e.** Choose individuals who will test plan regularly and act in the event of a disaster

_____**3.** Understand DR options:

- _____**a.** Determine how far to get the data out of the data center.
- _____**b.** Will the data center be accessible at the same time as the disaster.
- _____**c.** Determine the process to backup and/or replicate data off-site.
- _____**d.** Determine the process to recreate an environment off-site.

_____**4.** Audit providers:

- _____**a.** Compare list of providers with internal list of requirements.
- _____**b.** Understand range of data protection solutions offered
- _____**c.** Assess proximity (power grid/communications and contingencies).
- _____**d.** Data center hardening features and their DR contingencies.

_____**5.** Record findings, implement/test, and revise if/as necessary:

- _____**a.** Documentation is the heart of your plan.
- _____**b.** Test and adjust plan as necessary, record findings.
- _____**c.** As the environment changes and business needs change, revise the plan and test again.

different procedures as both present vastly diverse paths when bringing systems back up.

While both planned and unplanned downtime can be stressful, planned downtime must be finished on time. Unplanned is the worst. Unplanned can be good for teaching troubleshooting techniques to junior IT staff, but can be very frustrating to the workforce. The authors see fewer and fewer techs with troubleshooting experience, and more and more senior techs launching their own consultancies. The biggest cost is how it affects the customers and the impressions of the company that a severe outage can make on the organization's customers and clients. Planning, having people on staff with good troubleshooting skills, and documenting how the issue was found and fixed will help resolve the issue faster next time.

Matching the Response to the Threat

Separate each of your significant processes into one of three categories: Mission Critical, Business Critical or Organizationally Critical. By classifying processes into categories, you are able to define which parts of the organization would be recovered first in the event of an outage or disaster. How long can your organization or group live without access to a particular system? Should this system fail, how much data can the business realistically handle losing? Define, succinctly, what the organization considers a disastrously disruptive event and set the maximum amount of time you can go without access to your system. Then set the acceptable amount of data loss from the most recent backup, or replication. Repeat this step for each system and you will soon realize which systems have the highest priorities and highest impact. Look back in history and identify types of outages the firm has experienced and how those outages were dealt with. If one is more relevant than another, plan for that incident first.

3. THE BUSINESS IMPACT ASSESSMENT (BIA)

A business impact assessment is a solution that determines critical business processes based on their impact during a disruption. An organization must define resilience requirements, justify business continuity investments, and identify a robust risk mitigation strategy. Unplanned disruptions can be costly, resulting in major losses, customer dissatisfaction, and compliance issues. To counter such risks, developing an effective, end-to-end business resilience plan is a necessary component to business continuity and recovery solutions.

Identifying Business-Critical Activities

An organization must have a thorough understanding of the critical business processes and the tolerance of a business outage to define objectives to succeed in the event of an outage. A successful solution employs a vertical and horizontal, or top/down approach to understand, identify, and map critical business processes, functions, IT systems, resource dependencies, and delivery channels. The organization must analyze the cost of disruptions and place them into resilience tiers to assist in defining operational availability and disaster recovery requirements from a business perspective.

Additionally, Recovery Point Objectives (RPOs) and Recovery Time Objectives (RTOs) are perhaps the most important key metrics when architecting a disaster recovery solution. An RTO is the amount of time it takes to recover from a disaster event, and an RPO is the amount of data, measured in time, that your organization lost from that same event. The two business-driven metrics will set the stage for:

- Media chosen to recover (disk, tape, etc.)
- Location where data is being recovered
- Size of the recovery infrastructure and staff needed

Keep in mind that there are several intricacies to consider when assessing RTOs and RPOs. First, the objective in both stands for "objective" and should be defined as the target. If an RPO is five hours, then the architecture must ensure data loss of five hours or less. Therefore, when testing or recovering from a disaster, document and track actual thresholds achieved, including recovery point and recovery time. In many test cases, the time to recover does not meet the objective due to overhead time. Examples of overhead time are as follows:

- Selection of staff and determination in DR teams
- Declaration of the disaster and logistics to the recovery site
- Consideration of massive chaos is involved in initiating a recovery from a disaster event

When tracking and documenting actual versus objective, especially during testing, you will understand what is being accomplished in a given period of time. Figure 55.2 illustrates a flowchart of conflict resolution in the BIA and shows how time can be calculated when following the flow of the dependencies. Ultimately, this will allow a firm to defend future investment by honing your recovery methodologies and processes to better meet or exceed those objectives. Once the recovered data is made available and back to the application, the end users and owners of the applications only understand the RPO and RTO specific to usability of the application with an understood and acceptable amount of data loss in a specified amount of time.

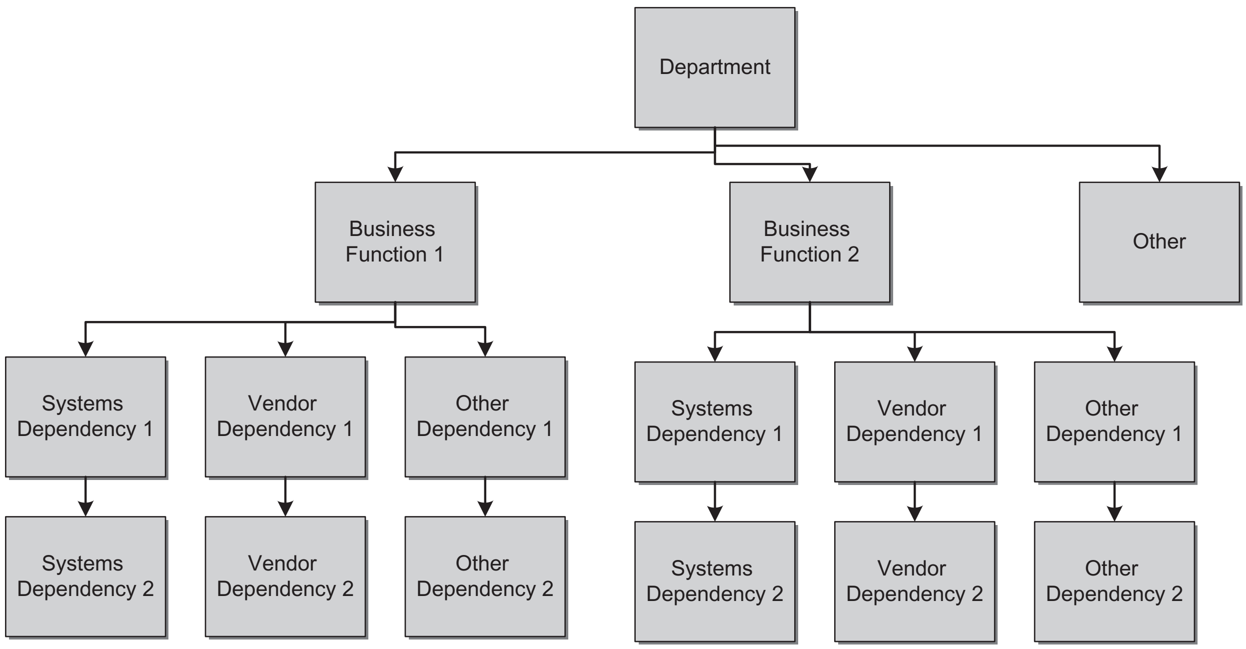

FIGURE 55.2 Flowchart illustrating the formula used to calculate the time a department receives items and performs actions prior to passing onto another department.

Specifying Required IT Support from Technical Staff

There are challenges associated with managing a high-density infrastructure coupled with the technology each department integrates into that infrastructure. To meet the continually increasing demand for faster, better, and more powerful technology, IT directors are deploying high-density equipment with great processing powers encompassing a small footprint in the data center.

Incongruent IT teams include storage, server, network, and application teams; all understand their specific roles in recovering from a disaster, which is why tests are so crucial. However, once the infrastructure is recovered with the associated application data, many more tasks are required to make the application usable and available to the end users. Consider, for example, what the DBAs need to do to the databases and what the application and software teams need to do in order to validate functionality. Thus, having these objects defined and metrics in place will help with the testing and checkpoints in the recovery process to ensure that the RTOs and RPOs are met successfully.

Designing Recovery Solutions

Many kinds of “disasters” can occur in business. Typically, one thinks mostly of natural disasters when one thinks of disasters. To do this when planning a disaster recovery solution is a fatal mistake. For example, consider a small company (or possibly even a large company!) where one or a small number of people control access to all data. Perhaps only one person has access to critical systems that, one day, may require reconfiguration or repair. What if that day comes sooner than expected, and what if that person was involved in a fatal car accident on the way to work? This sort of scenario and myriad others plague the information technology industry. The amount of risk tied up in IT director fiefdoms could, if exercised by a wide-scale disaster one day, bring about a nationwide business calamity. Think about the assorted systems that could be affected by the following “disasters:”

- Loss of bidirectional communication
- Loss of Internet connectivity
- Data loss
- Life lost

The final point, while not directly related to information technology and the preservation of business continuity through tragic, business-altering events is included because, at the heart of all the systems exist the human beings who operate and understand them. Recovery solutions should consider the human element. More importantly, a disaster recovery should be able to do just what the name implies—it should allow complete recovery, if not business continuity, through any disaster.

Consider, for example, a software company called Knowledge Inc. that provides critical software services to many of the Fortune 500 companies. On a Friday afternoon, a terrorist attack destroys their one, and only, location. The 400 + people who ran the company, except for those who were out sick or were on the road, are no more. Granted, the owner of the company has nothing to worry about anymore; he was in his office, but those 300 Fortune 500 companies, what about them? From their perspective, they are likely asking themselves why they never asked to see the DR plan for Knowledge Inc. They should have asked about the business recovery plan. Ostensibly, then, a DR plan contains two parts:

- Technology and data redundancy
- Business recovery

No business should ever *close down* due to a disaster. Yes, closing a business's books and winding down after a disaster could be the outcome of a disaster, but that should be a business decision, not a forced event. That is, the disaster itself, followed by a poorly executed or nonexistent DR plan, should not be a business-ending event. Closing the business or selling its assets may be the decision made by survivors and beneficiaries, but by preserving the business through proper DR planning, this should be just one of many options, not the only option after a disaster. As intimated earlier, disasters come in many forms, which can be loosely grouped into three categories:

1. Force Majeure
2. Conditional
3. Human

Force Majeure, or catastrophe, is obvious. Events such as hurricanes, earthquakes, fire, flood, war, volcanic eruptions, and terrorist acts all fall into this category.

Conditional is less obvious and revolves around the circumstances of an unexpected change in infrastructure conditions. For example, on a Monday afternoon, the Internet "goes down." Service doesn't' resume until Wednesday evening because it took that long for the service provider to find the problem. In another example, a construction crew saws through all three trunks that service the city of Chicago. As a result, 99% of the city loses its Internet. The other 1%? They had a recovery plan that included routing phones and Internet through a satellite dish on their roof.

The human category means loss of life and the business impact. For example, what if a strange new virus decimated more than half the organization's staff, and for some strange reason, it wiped out all but the most itinerant staff members, who have little knowledge of operations. A solid DR plan will consider that a disaster can occur, and all infrastructure may remain intact.

Establishing a Disaster Recovery Site

Once a disaster recovery plan has been created that includes both fail and no-fail infrastructure circumstances, a plan must be made that allows for varying degrees of infrastructure failure. For example, consider the conditions that must exist before someone says "Break out the black book!" and the organization *shifts* its mind-set into one of disaster recovery. For example, consider the following course of events:

1. The Internet goes down.
2. IT fails to back up Internet connections (there are three alternative paths to the Internet). Each path fails.
3. A DR link to the data center is powered up and established. This link is a point-to-point optical wireless linkup to the data center. There is no Internet at the data center either.
4. The DR link to the failover data center is powered up and established. This data center is also down.
5. Nobody knows what is happening yet, but one thing is certain: While the plan was okay, because there was even an alternative, nonphysical link to two data centers, one that was a failover site, it didn't help because the DR data center site was only a couple of miles from the primary.

In the event of a disaster, DR sites should be as logically separated from a catastrophe point of view as possible. To establish what makes a good DR site, let's explore disaster a little bit.

Site Choices: Configuration and Acquisition

Since this is a book about computer and information security, and not about business alternative planning, these next sections will focus primarily on force majeure and conditional disasters. The assumption it makes is that the business critical functions have been deemed complex and necessary enough that a geographically disparate location is desirable and necessary. For many, disaster recovery is about backup planning. A distinction between the two must be made. Backup and recovery addresses one thing, and only one thing: For example, a hacker accesses the system and deletes a small but critical table from a database. This is a backup and recovery option. You simply restore from backup, and you are up and running again. Disaster recovery is more severe, and it implies that the recovery of data after an incident that destroys equipment or data in tandem with an event of some sort has rendered equipment and communications at a particular site unusable. In this case the definition of unusable is one of a business nature:

- DR definition of *unusable*: Equipment or data or communications that are not functioning for such a length

of time as to render irreparable damage to business revenues or relationships.

- *Unusable*, then, in the business sense, must be taken in the context of this sentence.
- Disaster recovery is a sequence of events that, regardless of extenuating circumstances, will restore the full functionality of data, communications, or equipment, located at some one site or many sites, that has been rendered unusable by some event.

Over time, some piece of equipment may become unserviceable, but in terms of disaster recovery, something is *unusable* only if its unserviceability inflicts damage on the business. Disaster recovery assumes one thing is true: that a major, business critical function has ceased operation due to one of the aforementioned reasons, and that it can no longer continue.

The following list details a number of disasters and chooses alternative locations. In the end, one may consider that the disaster is too unlikely to occur, and that if the disaster were to occur (such as an asteroid strike), there would likely be no point in continuing business anyway— simply surviving will be everyone's concern, and whether or not customers can purchase concert tickets will be moot if nobody is going to be going to concerts any time soon. Table 55.1 provides a sample listing of DR failover locations, the disaster that occurs, and the reason why it is a bad choice. This table seeks to provide a thought experiment framework whereby a planner may base a similar table for her location.

Choosing Suppliers: In-House Versus Third Party

As evidenced by Table 55.1, the complexity of choosing a DR location that is a perfect *ying* to your primary locations *yang* is not an easy task. If one assumes that the third-party provider has been in business for a while, has experience in the field, and is not just an investor who purchased an underground quarry in Kansas City and simply didn't know what to do with it, then the primary reason to contract a DR provider will be one of reliability.

Furthermore, the DR provider will host *other* companies, which means that they will likely be performing the sort of monthly and manual testing of their failover electrical and uplink capabilities that is required. This results in a savings due to the economy of scale. A company that has to test its systems understands that testing takes time, is expensive, and may result in unanticipated damage to equipment should a faulty failover mechanism result in a massive surge through the power grid.

Typically, businesses that aren't savvy or interested in the facts of disasters— that they do happen, and they can happen to them—may make a rather cursory attempt at DR. They may blend some non-DR site functions with the DR site. The mistake they make in doing this relates directly to redundancy—inherent to the DR strategy is that, essentially, both sites require each other to act as backup. If the DR site is being used, and it fails, it would need to failover to the primary site. Organizations that are greatly concerned about business

TABLE 55.1 The Portland Example Serves to Illustrate that While a Disaster Recovery Planned Site may Appear to be Perfectly Acceptable, even if Affected by Collateral After-Affects, the type of Infrastructure and the Routing of the Trunks, all May Play a Part. The ENTIRE Infrastructure of the Environment, and all the Unknown Interdependencies should be thoroughly Uncovered, Explored, and Understood.

Primary Site	Disaster	DR Location	Pass/Fail
Quad Cities	Flood	St. Louis	It flooded too.
Chicago	Military strike	New York	Communications in New York were also targeted.
Miami	Hurricane	Chicago	Pass.
San Francisco	Earthquake	San Jose	Fail. San Jose is under water.
Portland	Volcano	Seattle	Fail. The Seattle site depends on optical wireless, which are due to Portland's ash cloud and northerly winds.
New York	Tsunami	San Diego	Pass.
St. Louis	Tornado	Undisclosed location in Nevada	Pass. The use of a hardened, undisclosed location protects against additional threats, such as terrorist or military action, that may strike multiple communication centers simultaneously. With satellite uplinks, this location is ideal against myriad threats.

continuity will segregate business functions completely. When contracting a vendor to handle DR, the business will drive the requirements. Things like email, database applications, HR, and finance systems may not have the same impact of loss as, for example, a Web site that takes customer orders.

When building a DR plan, the planners must consider the scope of the disaster as well, how the vendor charges, and whether or not multiple vendors are required to fully comply with business needs. For example, for some companies, it is perfectly acceptable that employees could work for home in case the DR triggering event also closed the physical office. Other companies may have differing compliance issues and may require a secure facility. They may even require that employees travel to a distant location and work there. Now, arrangements have to be made for both PC access to network systems and food and lodging. This author recommends a nice resort that has conference center capabilities that could be set up to provide workstations. Do bear in mind that some employees will require family housing. Choosing to provision DR through in-house versus choosing an external vendor requires comparing and determining a number of factors:

- Skills—Decide whether or not the IT team has the skills and the time (or can hire someone.)
- Location—Determine whether or not the location is suitable. For example, a large law firm may already have multiple data centers. It begins to make sense to handle disaster recovery internally if the company is not segmented in such a way that use of its multiple data centers will cause internal turmoil (this speaks to the IT fiefdoms alluded to earlier.)
- Estimated downtime—The definition of a disaster has already been described as involving the length of the downtime. How much further past the qualifying outage window is tolerable? If the best that internal resources can do is 24 hours to get a remote DR site functional and the requirement is 2 hours, outside help should be sought.

Figure 55.3 diagrams a failover site. Data flows are unidirectional *to* the DR site. It is a common fallacy that the DR site can also provide some functionality to the enterprise and serve as more than just a graveyard for servers, waiting for the day they must spring to life and perform a critical duty.

Specifying Equipment

The challenge of a DR site is primarily cost, followed closely by configuration. Setting it up, planning redundancy, creating strategies for rerouting voice, messaging,

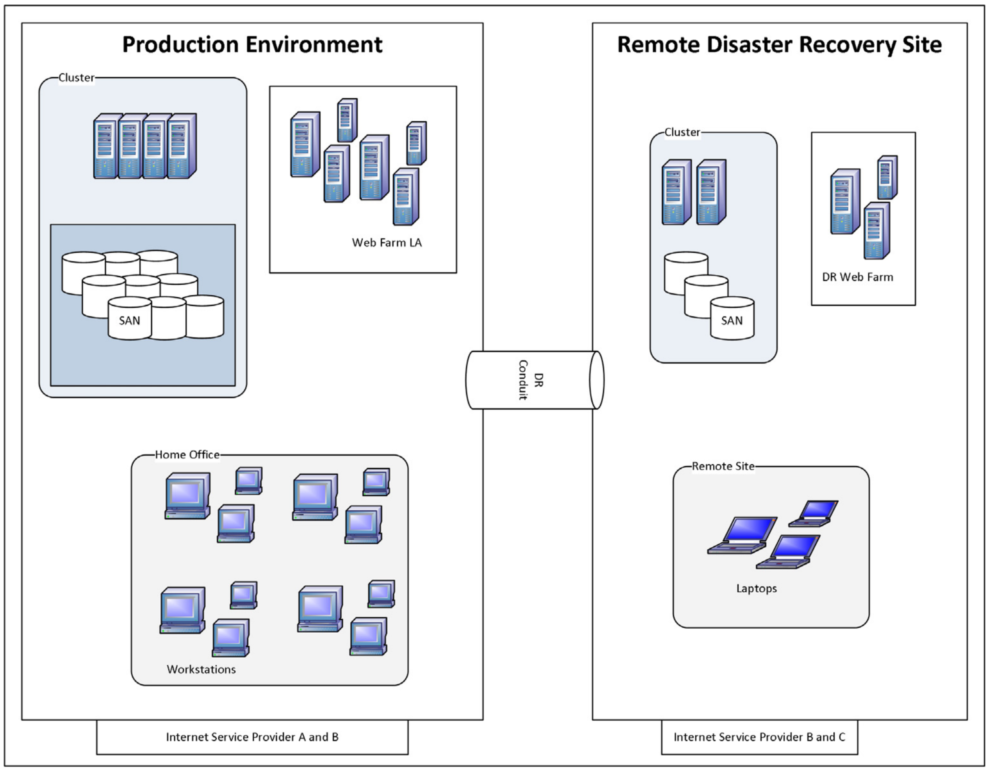

FIGURE 55.3 In a DR site, one can expect to see a slimming down of the amount of equipment needed. Configuring applications to work in such an environment will be a balance between labor costs and estimates of configuration time and the cost of additional servers. Rewriting application code to force a distributed application to work with a reduced server requirement may not be cost effective.

email, delivery of goods, and so on are things that can be written and kept within arm's reach of all employees. ALL employees should be aware of the DR plan. No single employee should be left wondering what his role is during a disaster.

Configuration and cost are closely related. In just one example (of many similar), consider a complex federated database where many applications and many databases commingle information and exist in harmony on a home-grown system across 30 or 40 SQL servers. Picking up something so complex, and moving it, is not a simple task. It may take many weeks of reconfiguration to get such as system to be functional at the DR site. The complexity of an application and the ease of setting it up in a DR site should always be considered *during the purchasing and application review phase*. Waiting until afterwards to think about the DR site can be a very costly mistake. A DR-ready application will be able to collapse down to just a couple of servers and will be able to provide core functionality, with additional functionality brought online with the addition of more servers as needed.

A DR site is a site that is to be used for a temporary period of time. Typically, the hope is that the DR failover will not be permanent. However, this should be a planned contingency—that it will be permanent and that you may need to rapidly scale the environment. This is not to say that a DR site should be a fully functional, duplicate site of the primary site that failed. Rather, it should be able to support essential business functions. Suppose, for example, an enterprise that hosts a document review platform. Many people would like to access the system, but in the contract with its clients, the business is only committed to support minimal, required activities, and they are listed. Contractually, activity should be restricted. Only known, business-critical activity should be conducted. Users should only be performing activities that are business critical for them or their customers.

From an equipment purchasing standpoint, then, only minimal hardware need be purchased. Some companies may even refer to their DR site as "the graveyard" and the DR plan as a "Dawn of the Dead" plan. However, from a strategic standpoint, rack space MUST be available for rapid growth. Should the disaster become lengthy, or should the outage be permanent, the enterprise must be able to scale rapidly. Many business computing sales companies will configure a "standing order." This is something that, for a price, can be held in a sort of "escrow" until needed. When an outage becomes extensive, or permanent, or is recognized as being permanent the moment it happened, then pulling the trigger on such an order could actually be automatic and scripted in the failover plan. After all, in the event of a Dawn of the Dead, the graveyard will need to be fed more brains.

4. SUMMARY

Creating an effective, risk-biased, deployable DR plan that carefully considers human and technology interests takes time and attention. The solution to just about all DR issues that crop up will be to *spend more money*. This is where the art of it, and the experience of the designers, will either make or break the plan. Inexperienced planners may make assumptions and will overlook critical aspects of how to deploy the plan. They may not take it seriously, but as has been seen in recent history, *expect the worst*. Maintaining a heightened state of awareness is the rule of the day. Experienced IT professionals will be able to design a plan that is effective.

These authors recommend that a disaster recovery team be made up of the most senior people in the company—people who have been with the company for a long time and know its every system inside and out. These are people who should have ten or more years of experience in IT, if not with the company itself. These are the people who can ensure that, should a disaster occur, business will continue—because they are the ones doing this work already— they are the ones who are called when something is broken and nobody else can get it right. They are the ones who can unclog a plugged firewall, who have the part number for that odd LED in the service rack memorized, and they are the ones who could, if needed, rebuild the entire infrastructure from scratch, preferably while they sleep. Essentially, that is what DR is. It is an essential-function rebuilding of the entire company. Asking it to be anything less is simply asking for failure.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Disaster recovery (DR), not unlike the plugged sink, is another task that many organizations fail to consider until after much of the technology groundwork has been laid, the corporation is profitable, and suddenly someone realizes that *not* having a DR site is a serious risk to the business.
2. True or False? A general component of a disaster recovery (DR) plan is for the committee to assess conceivable risks to the organization that could result in the disasters or emergency situations themselves.
3. True or False? Enterprise Risk Management (ERM) is not a template that can be given to every company to meet their needs and fit their business structure.

4. True or False? Downtime presents moderate consequences for businesses, no matter what their function may be.
5. True or False? A business impact assessment is a solution that determines critical business processes based on their impact during a disruption.

Multiple Choice

1. An organization must have a thorough understanding of the ______ and the tolerance of a business outage to define objectives to succeed in the event of an outage.
   A. qualitative analysis
   B. vulnerabilities
   C. critical business processes
   D. malformed request DoS
   E. data controller
2. There are challenges associated with managing a ________, coupled with the technology each department integrates into that infrastructure.
   A. network attached storage (NAS)
   B. risk assessment
   C. valid
   D. high-density infrastructure
   E. bait
3. There are many types of _________ that can occur in business.
   A. data minimization
   B. fabric
   C. disasters
   D. risk communication
   E. security
4. Once a disaster recovery plan has been created that includes both fail and no-fail infrastructure circumstances, a plan must be made that allows for varying degrees of:
   A. risk management
   B. greedy strategy
   C. infrastructure failure
   D. SAN protocol
   E. taps
5. What are equipment or data or communications that are not functioning for such a length of time as to render irreparable damage to business revenues or relationships?
   A. Irrelevant
   B. Tape library
   C. IP storage access
   D. Configuration file
   E. Unusable

EXERCISE

Problem

What are the differences among a Continuity of Operations Plan (COOP), a Business Continuity Plan (BCP), a Critical Infrastructure Protection (CIP) Plan, a Disaster Recovery Plan (DRP), an Information System Contingency Plan (ISCP), a Cyber Incident Response Plan, and an Occupant Emergency Plan (OEP)?

Hands-On Projects

Project

What type of alternate site should an organization choose as a disaster recovery strategy?

Case Projects

Problem

When an event occurs, who should be notified?

Optional Team Case Project

Problem

With what other activities should the ISCP and the recovery solutions be coordinated?

Chapter 56

Biometrics

Luther Martin
Voltage Security

Biometrics is the analysis of biological observations and phenomena. People routinely use biometrics to recognize other people, commonly using the shape of a face or the sound of a voice to do so. Biometrics can also be used to create automated ways of recognizing a person based on her physiological or behavioral characteristics. Using biometrics as the basis of technologies that can be used to recognize people is not a new idea; there is evidence that fingerprints were used to sign official contracts in China as early as AD 700 and may have been used by ancient Babylonian scribes to sign cuneiform tablets as early as 2000 BC.[1] In both of these cases, a fingerprint was pressed in clay to form a distinctive mark that could characterize a particular person. It is likely that the sophistication of the techniques used to analyze biometric data has increased over the past 4000 years, but the principles have remained essentially the same.

Using biometrics in security applications is certainly appealing. Determining a person's identity through the presence of a physical object such as a key or access card has the problem that the physical token can be lost or stolen. Shared secrets such as passwords can be forgotten. Determining a person's identity using biometrics seems an attractive alternative. It allows an identity to be determined directly from characteristics of the person. It is generally impossible for people to lose or forget their biometric data, so many of the problems that other means of verifying an identity are essentially eliminated if biometrics can be used in this role.

Not all biometric data is suitable for use in security applications, however. To be useful, such biometric data should be as unique as possible (uniqueness), should occur in as many people as possible (universality), should stay relatively constant over time (permanence), and should be able to be measured easily (measurability) and without causing undue inconvenience or distress to a user (acceptability). Examples of technologies that seem to meet these criteria to varying degrees are those that recognize a person based on his DNA, geometry of his face, fingerprints, hand geometry, iris pattern, retina pattern, handwriting, or voice. Many others are also possible. Not all biometrics are equally suited for use in security applications. Table 56.1 compares the properties of selected biometric technologies, rating each property as high, medium, or low. This table shows that there is no "best" biometric for security applications. Though this is true, each biometric has a set of uses for which its particular properties make it more attractive than the alternatives.

Biometrics systems can be used as a means of authenticating a user. When they are used in this way, a user presents his biometric data along with his identity, and the biometric system decides whether or not the biometric data presented is correct for that identity. Biometrics used as a method of authentication can be very useful, but authentication systems based on biometrics also have very different properties from other authentication technologies, and these differences should be understood before biometrics are used as part of an information security system.

Systems based on biometrics can also be used as a means of identification. When they are used in this way, captured biometric data is compared to entries in a database, and the biometric system determines whether or not the biometric data presented matches any of these existing entries. When biometrics are used for identification, they have a property that many other identification systems do not have. In particular, biometrics do not always require the active participation of a subject. While a user always needs to enter her password when the password is used to authenticate her, it is possible to capture biometric data without the user's active involvement, perhaps even without her knowledge. This lets data be used in ways that other systems cannot. It is possible to automatically capture images of customers in a bank, for example, and to use the images to help identify people who are known to commit check fraud. Or it is possible to automatically capture images of airline passengers in an airport and use the images to help identify suspicious travelers.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00056-8

TABLE 56.1 Overview of Selected Biometric Technologies.

Biometric	Uniqueness	Universality	Permanence	Measurability	Acceptability
DNA	High	High	High	Low	Low
Face geometry	Low	High	Medium	High	High
Fingerprint	High	Medium	High	Medium	Medium
Hand geometry	Medium	Medium	Medium	High	Medium
Iris	High	High	High	Medium	Low
Retina	High	High	Medium	Low	Low
Signature dynamics	Low	Medium	Low	High	High
Voice	Low	Medium	Low	Medium	High

The use of biometrics for identification also has the potential to pose serious privacy issues. The interests of governments and individual citizens are often at odds. Law enforcement agencies might want to be able to track the movements of certain people, and the automated use of biometrics for identification can certainly support this goal. On the other hand, it is unlikely that most people would approve of law enforcement having a database that contains detailed information about their travels. Similarly, tax authorities might want to track all business dealings to ensure that they collect all the revenue they are due, but it seems unlikely that most people would approve of government agencies having a database that tracks all merchants they have had dealings with, even if no purchases were made. Using some biometrics may also inherently provide access to much more information that is needed to just identify a person. DNA, for example, can used to identify people, but it can also be used to determine information about genetic conditions that are irrelevant to the identification process. But if a user needs to provide a DNA sample as a means of identification, the same DNA sample could be used to determine genetic information that the user might rather have kept private.

Designing biometric systems has been dubbed a "grand challenge" by researchers,[2] indicating that a significant level of research will be required before it will be possible for real systems to approach the performance that is expected of the technology, but one that also has the possibility for broad scientific and economic impact when technology finally reaches that level. So, although biometric systems are useful today, we should expect to see them become even more useful in the future and for the technology to eventually become fairly commonly used.

1. RELEVANT STANDARDS

The American National Standard (ANS) X9.84, "Biometric Information Management and Security for the Financial Services Industry," is one of the leading standards that provide an overview of biometrics and their use in information security systems. It is a good high-level discussion of biometric systems, and the description of the technology in this chapter roughly follows the framework defined by this standard. This standard is particularly useful to system architects and others concerned with a high-level view of security systems. On the other hand, this standard does not provide many details of how to implement such systems.

There are also several international (ISO/IEC) standards that cover the details of biometric systems with more detail than ANS X9.84 does. These are listed in Table 56.2. These standards provide a good basis for implementing biometric systems and may be useful to both engineers and others who need to build a biometric system, and others who need the additional level of detail that ANS X9.84 does not provide. Many other ISO/IEC standards for biometric systems are currently under development that address other aspects of such systems, and in the next few years it is likely that the number of these standards that have been finalized will at least double from the number that are listed here. The JTC 1/SC 37 technical committee of the ISO is responsible for the development of these standards.

2. BIOMETRIC SYSTEM ARCHITECTURE

All biometric systems have a number of common subsystems. These are the following:

- A data capture subsystem
- A signal processing subsystem

TABLE 56.2 Current ISO/I EC Standards for Biometric Systems.

Standard	Title
ISO/IEC 19784-1:2006	Information technology – Biometric Application Programming Interface – Part 1: BioAPI Specification
ISO/IEC 19784-2:2007	Information technology – Biometric Application Programming Interface – Part 2: Biometric Archive Function Provider Interface

- A matching subsystem
- A data storage subsystem
- A decision subsystem

An additional subsystem, the adaptation subsystem, may be present in some biometric systems but not others.

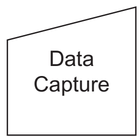

FIGURE 56.1 Symbol used to indicate a data capture subsystem.

Data Capture

A data capture subsystem collects captured biometric data from a user. To do this, it performs a measurement of some sort and creates machine-readable data from it. This could be an image of a fingerprint, a signal from a microphone, or readings from a special pen that takes measurements while it is being used. In each case, the captured biometric data usually needs to be processed in some way before it can be used in a decision algorithm. It is extremely rare for a biometric system to make a decision using an image of a fingerprint, for example. Instead, features that make fingerprints different from other fingerprints are extracted from such an image in the signal processing subsystem, and these features are then used in the matching subsystem. The symbol that is used to indicate a data capture subsystem is shown in Figure 56.1.

The performance of a data capture subsystem is greatly affected by the characteristics of the sensor that it uses. A signal processing subsystem may work very well with one type of sensor, but much less well with another type. Even if identical sensors are used in each data capture subsystem, the calibration of the sensors may need to be consistent to ensure the collection of data that works well in other subsystems.

Environmental conditions can also significantly affect the operation of a data capture subsystem. Dirty sensors

can result in images of fingerprints that are distorted or incomplete. Background noise can result in the collection of a data that makes it difficult for the signal processing subsystem to identify the features of a voice signal. Lighting can also affect any biometric data that is collected as an image so that an image collected against a gray background might not work as well as an image collected against a white background.

Because environmental conditions affect the quality and usefulness of captured biometric data, they also affect the performance of all the subsystems that rely on it. This means that it is essential to carry out all testing of biometric systems under conditions that duplicate the conditions under which the system will normally operate (see checklist, "An Agenda For Action For Biometrics Testing"). Just because a biometric system performs well in a testing laboratory when operated by well-trained users does not mean that it will perform well in real-world conditions. Because the data capture subsystem is typically the only one with which users directly interact, it is also the one that may require training of users to ensure that it provides useful data to the other subsystems.

Signal Processing

A signal processing subsystem takes the captured biometric data from a data capture subsystem and transforms the data into a form suitable for use in the matching subsystem. This transformed data is called a *reference*, or a *template* if it is stored in a data storage subsystem. A template is a type of reference, and it represents the average value that we expect to see for a particular user.

A signal processing subsystem may also analyze the quality of captured biometric data and reject data that is not of high enough quality. An image of a fingerprint that is not oriented correctly might be rejected, or a sample of speech that was collected with too much background noise might be rejected. The symbol that is used to indicate a signal processing subsystem is shown in Figure 56.2.

If the captured biometric data is not rejected, the signal processing subsystem then transforms the captured biometric data into a reference. In the case of fingerprints, for example, the signal processing subsystem may extract features such as the locations of branches and endpoints of the ridges that comprise a fingerprint. A biometric system that uses the speech of users to characterize them might convert the speech signal into frequency components using a Fourier transform and then look for patterns in the frequency components that uniquely characterize a particular speaker. A biometric that uses an image of a person's face might first look for large features such as the eyes, nose, and mouth and then look for distinctive features such as eyebrows or parts of the nose relative to the large ones, to uniquely identify a particular user. In any case, the output of the signal processing subsystem is the transformed data that comprises a reference. Although a reference contains information that has been extracted from captured biometric data, it may be possible to recover the captured biometric data, or a good approximation to it, from a template.[3]

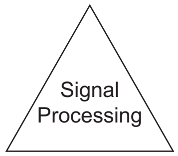

FIGURE 56.2 Symbol used to indicate a signal processing subsystem.

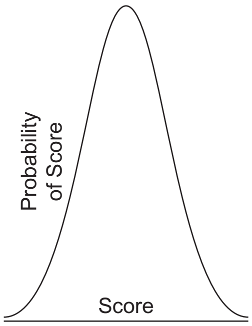

FIGURE 56.3 Distribution in comparison scores for a typical user.

Note that though several standards exist that define the format of biometric references for many technologies, these standards do not describe how references are obtained from captured biometric data. This means that there is still room for vendor innovation while remaining in compliance with existing standards.

Matching

A matching subsystem receives a reference from a signal processing subsystem and then compares the reference with a template from a data storage subsystem. The output of the matching subsystem is a numeric value called a *comparison score* that indicates how closely the two match.

Random variations occur in a data capture subsystem when it is used. This means that the reference created from the captured data is different each time, even for the same user. This makes the comparison score created for a particular user different each time they use the system, with random variations occurring around some average value. This concept is shown in Figure 56.3, in which the distribution of comparison scores that are calculated from

An Agenda for Action for Biometrics Testing

Steps in technical requirements for biometrics testing accreditation (Check All Tasks Completed):

Personnel:

_____**1.** The laboratory shall maintain competent administrative and technical staff that are :

_____**a.** Knowledgeable of all biometrics standards pertaining to the specific tests found on the laboratory's scope(s) of accreditation.

_____**b.** Familiar with the biometrics terminology, biometrics modalities, biometrics systems and sub-systems.

_____**c.** Familiar with the "acceptable use" (collection, storage, handling, etc.) of Personally Identifiable Information (PII) as described in federal and state laws.

_____**d.** Familiar with the biometrics products testing protocols, procedures and tools, when applicable.

_____**e.** Familiar with human-crew interaction and human-crew rights and responsibilities, when applicable.

_____**2.** The laboratory shall maintain a list of personnel designated to fulfill requirements including:

_____**a.** Laboratory's director

_____**b.** Authorized Representative

_____**c.** Approved Signatories

_____**d.** team leaders

_____**e.** Key technical persons in the laboratory

_____**3.** The laboratory shall identify a staff member as quality manager with overall responsibility for quality assurance and for maintenance of the quality manual. An individual may be assigned or appointed to serve in more than one position; however, to the extent possible, the laboratory director and the quality manager positions should be independently staffed.

_____**4.** The laboratory key technical personnel who conduct biometrics products testing activities shall have at least a Bachelor of Science in Computer Science, Computer Engineering, Electrical Engineering, Human Factors or similar technical discipline or equivalent experience.

_____**5.** Laboratory staff collectively shall have knowledge of or experience in the following areas:

_____**a.** Biometrics modalities available.

_____**b.** Design/analysis of biometrics systems and sub-systems.

_____**c.** Database systems.

_____**d.** Biometrics products testing protocols and procedures.

_____**e.** Biometrics data structures.

_____**f.** Biometrics standards and special publications referenced in this handbook.

_____**g.** Familiarity with operating systems under which the biometrics systems are operating.

_____**h.** Any specific technology upon which testing is conducted.

_____**6.** The laboratory shall have documented a detailed description of its training program for new and current staff members. Each new staff member shall be trained for assigned duties.

_____**7.** The training program shall be updated and current staff members shall be retrained when relevant standards or scope of accreditation changes, or when the individuals are assigned new responsibilities. Each staff member may receive training for assigned duties either through on-the-job training, formal classroom study, attendance at conferences, or another appropriate mechanism.

_____**8.** Training materials that are maintained within the laboratory shall be kept up-to-date.

_____**9.** The laboratory shall have a competency review program and procedures for the evaluation and maintenance of the competency of each staff member for each test method the staff member is authorized to conduct.

_____**10.** An evaluation and an observation of performance shall be conducted annually for each staff member by the immediate supervisor or a designee appointed by the laboratory director.

_____**11.** A record of the annual evaluation of each staff member shall be dated and signed by the supervisor and the employee.

_____**12.** A description of competency review programs shall be maintained in the management system.

_____**13.** If the mechanism by which the laboratory employs staff members is through contracting, any key personnel who are contractors shall be identified and listed in the laboratory's application for accreditation.

_____**14.** If the mechanism by which the laboratory employs staff members is through contracting, any key personnel who are contractors shall be identified and listed in the laboratory's application for accreditation.

_____**15.** The laboratory personnel who handle PII documents shall obey all laboratory policies and procedures that implement the federal and state privacy laws that stress the "acceptable uses" of PII.

repeated captures of biometric data from a single user are random. Such random data tend to be close to an average value every time that they are calculated from captured biometric data but not exactly the average value.

This is much like the case we get in other situations where observed data has a random component. Suppose that we flip a fair coin 100 times and count how many times the result “heads” appears. We expect to see this result an average of 50 times, but this average value actually occurs fairly rarely; exactly 50 out of 100 flips coming up heads happen less than 8% of the time. On the other hand, the number of heads will usually be not too far from the average value of 50, with the number being between 40 and 60 more than 95% of the time. Similarly, with biometrics, captured data will probably be close, but not identical, to an average value, and it will also not be too different from the average value.

The comparison score calculated by a matching subsystem is passed to a decision subsystem, where it is used to make a decision about the identity of the person who was the source of the biometric data. The symbol that is used to indicate a matching subsystem is shown in Figure 56.4.

Data Storage

A data storage subsystem stores templates that are used by the matching subsystem. The symbol that is used to indicate a data storage subsystem is shown in Figure 56.5.

A database is one obvious candidate for a place to store templates, but it is possible to store a template on a portable data storage device such as a chip card or a smart card. The relative strengths and weaknesses of different ways of doing this are discussed in the section on security considerations.

Decision

A decision subsystem takes a comparison score that is the output of a matching subsystem and returns a binary *yes* or *no* decision from it. This decision indicates whether or not the matching subsystem made a comparison which resulted in a match or not. The value *yes* is returned if the comparison was probably a match; the value *no* is returned is the comparison was probably not a match. The symbol that is used to indicate a decision subsystem is shown in Figure 56.6.

To make a *yes* or *no* decision, a decision subsystem compares a comparison score with a parameter called a *threshold*. The threshold value represents a measure of how good a comparison needs to be to be considered a match. If the comparison score is less than or equal to the threshold value then the decision subsystem returns the value *yes*. If the comparison score is greater than the threshold, it returns the value *no*. Comparison scores that will result in a *yes* or *no* response from a decision subsystem are shown in Figure 56.7. Comparison scores in the gray area of this illustration are close to the average value and result in a *yes*, whereas comparison scores that are outside the gray area are too far from the average value and result in a *no*. In Figure 56.7, the threshold value defines how far the gray area extends from the central average value. If the threshold is decreased, the size of the gray area will get narrower and decrease in size so that fewer comparison scores result in a *yes* answer. If the threshold is increased, the gray area will get wider and increase in size so that more comparison scores result in a *yes* answer.

Errors may occur in any decision subsystem. There are two general types of errors that can occur. In one

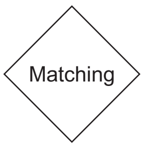

FIGURE 56.4 Symbol used to indicate a matching subsystem.

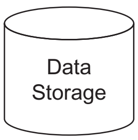

FIGURE 56.5 Symbol used to indicate a data storage subsystem.

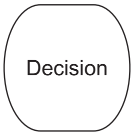

FIGURE 56.6 Symbol used to indicate a decision subsystem.

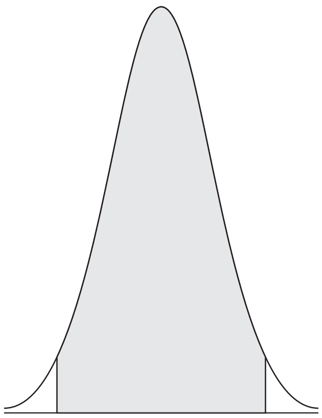

FIGURE 56.7 Comparison scores close to the average that result in a *yes* decision.

case, a decision subsystem makes the incorrect decision of *no* instead of *yes*. In this case, a user is indeed who she claims to be, but large random errors occur in the data capture subsystem and cause her to be incorrectly rejected. This type of error might result in the legitimate user Alice inaccurately failing to authenticate as herself.

This class of error is known as a *type*-1 error by statisticians,[4] a term that would almost certainly be a contender for an award for the least meaningful terminology ever invented if such an award existed. It was once called *false rejection* by biometrics researchers and vendors, a term that has more recently been replaced by the term *false nonmatch*. One way in which the accuracy of biometric systems is now typically quantified is by their false nonmatch rate (FNMR), a value that estimates the probability of the biometric system making a type-1 error in its decision subsystem.

In the second case, a decision subsystem incorrectly returns a *yes* instead of a no. In this case, random errors occur that let a user be erroneously recognized as a different user. This might happen if the user Alice tries to authenticate as the user Bob, for example. This class of error is known as a *type*-2 error by statisticians.[5] It was once called *false acceptance* by biometrics researchers and vendors, a term that has been more recently been replaced by the term *false match*. This leads to quantifying the accuracy of biometrics by their false match rate (FMR), a value that estimates the probability of the biometric system making a type-2 error.

For a particular biometric technology, it is impossible to simultaneously reduce both the FNMR and the FMR, although improving the technology does make it possible to do this. If the parameters used in a matching subsystem are changed so that the FNMR decreases, the FMR rate must increase; if the parameters used in a matching subsystem are changed so that the FMR decreases, the FNMR must increase. This relationship follows from the nature of the statistical tests that are performed by the decision subsystem and is not limited to just biometric systems. Any system that makes a decision based on statistical data will have the same property. The reason for this is shown in Figures 56.8 and 56.9.

Suppose that we have two users of a biometric system: Alice and Bob, whose comparison scores are distributed as shown in Figure 56.8. Note that the distributions of these values overlap so that in the area where they overlap, the comparison score could have come from either

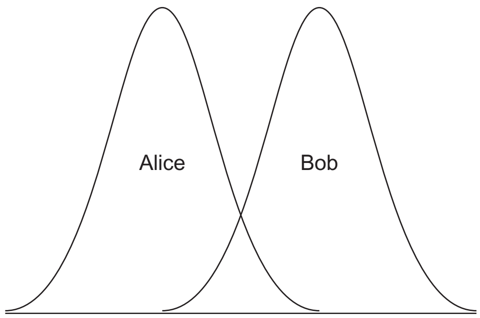

FIGURE 56.8 Overlap in possible comparison scores for Alice and Bob.

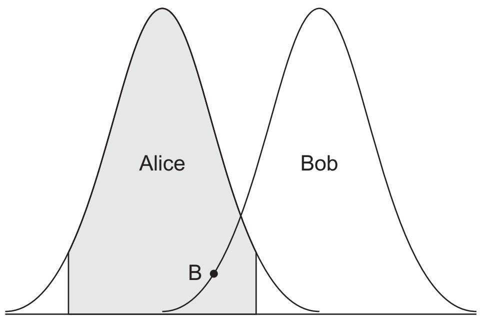

FIGURE 56.9 Type-2 error that causes a false match.

Alice or Bob, but we cannot tell which. If the average values that we expect for Alice and Bob are far enough apart, the chances of this happening may get extremely low, but even in such cases it is possible to have large enough errors creep into the data capture step to make even the rarest of errors possible.

Figure 56.9 shows how a false match can occur. Suppose that Bob uses our hypothetical biometric system but claims to be Alice when he does this, and the output of the matching subsystem is the point B that is shown in Figure 56.9. Because this point is close enough to the average that we expect from biometric data from Alice, the decision subsystem will erroneously decide that the biometric data that Bob presented is good enough to authenticate him as Alice. This is a false match, and it contributes to the FMR of the system.

Figure 56.10 shows how a false nonmatch can occur. Suppose that Alice uses our hypothetical biometric system and the output of the matching subsystem is the point A that is shown in Figure 56.10. Because this point is too far from the average that we expect when Alice uses the system, it is more likely to have come from someone else other than from Alice, and the decision subsystem will erroneously decide that the biometric data that Alice presented is probably not hers. This is a false nonmatch, and it contributes to the FNMR of the system.

Because the FNMR and FMR are related, the most meaningful way to represent the accuracy of a biometric

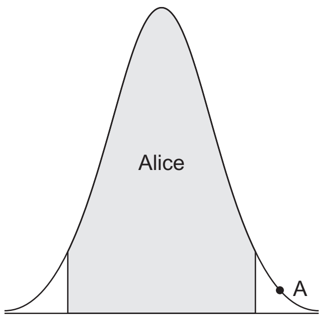

FIGURE 56.10 Type-1 error that causes a false nonmatch.

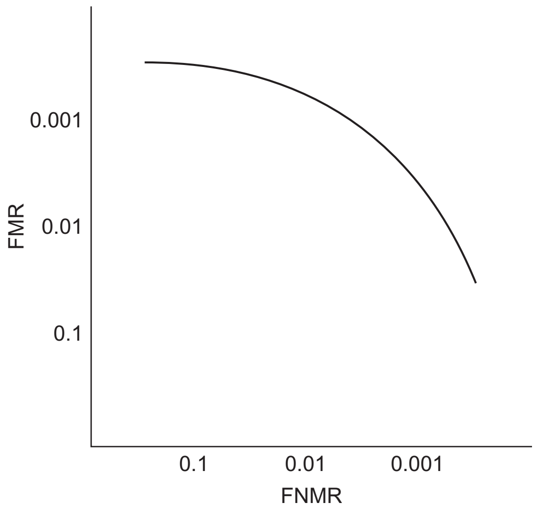

FIGURE 56.11 ROC for a hypothetical biometric system.

system is probably by showing the relationship between the two error rates. The relationship between the two is known by the term *receiver operating characteristic*, or ROC, a term that originated in the study of the sensitivity of radio receivers as their operating parameters change. Figure 56.11 shows an ROC curve for a hypothetical biometric. Such an ROC curve assumes that the only way in which the error rates are changed is by changing the threshold value that is used in the decision subsystem. Note that this ROC curve indicates that when the FMR increases the FNMR decreases, and vice versa.

By adjusting the threshold that a decision subsystem uses it is possible to make the FMR very low while allowing the FNMR to get very high or to allow the FMR to get very high while making the FNMR very low. Between these two extreme cases lies the case where the FMR and the FNMR are the same. This point is sometimes the equal error rate (EER) or crossover error rate (CER) and is often used to simplify the discussions of error rates for biometric systems.

Though using a single value does indeed make it easier to compare the performance of different biometric systems, it can also be somewhat misleading. In high-security applications like those used by government or military organizations, keeping unauthorized users out may be much more important than the inconvenience caused by a high FNMR. In consumer applications, like ATMs, it may be more important to keep the FNMR low. This can help avoid the anger and accompanying support costs of dealing with customers who are incorrectly denied access to their accounts. In such situations, a low FNMR may be more important than the higher security that a higher FMR would provide. The error rates that are acceptable are strongly dependent on how the technology is being used, so be wary of trying to understand the performance of a biometric system by only considering the CER.

There is no theoretical way to accurately estimate the FMR and FNMR of biometric systems, so all estimates of these error rates need to be made from empirical data. Because testing can be expensive, the sample sizes used in such testing are often relatively small, so the results may not be representative of larger and more general populations. This is further complicated by the fact that some of the error rates that such testing attempts to estimate are fairly low. This means that human error from mislabeling data or other mistakes that occur during testing may make a bigger contribution to the measured error rates than the errors caused by a decision subsystem. It may be possible to create a biometric system that makes an error roughly only one time in 1 million operations, for example, but it is unrealistic to expect such high accuracy from the people who handle the data in an experiment that tries to estimate such an error rate. And because there are no standardized sample sizes and test conditions for estimating these error rates, there can be a wide range of reliability of error rate estimates. In one study,[5] a biometric system that performed well in a laboratory setting when used by trained users ended up correctly identifying enrolled users only 51% of the time when it was tested in a pilot project under real-world conditions, perhaps inviting an unenviable comparison with a system that recognizes a person by his ability to flip a coin and have it come up heads. Because of these effects, estimates of error rates should be viewed with a healthy amount of skepticism, particularly when extremely low rates are claimed.

Adaptation

Some biometric data changes over time. This may result in matches with a template becoming worse and worse over time, which will increase the FNMR of a biometric system. One way to avoid the potential difficulties associated with having users eventually becoming unrecognizable is to update their template after a successful authentication.

This process is called *adaptation*, and it is done by an optional part of a biometric system called an adaptation subsystem. If an adaptation subsystem is present, the symbol shown in Figure 56.12 is used to indicate it.

FIGURE 56.12 Symbol used to indicate an adaptation subsystem.

3. USING BIOMETRIC SYSTEMS

There are three main operations that a biometric system can perform. These are the following.

- *Enrollment.* During this operation, a biometric system creates a template that is used in later authentication and identification operations. This template, along with an associated identity, is stored in a data storage subsystem.
- *Authentication.* During this operation, a biometric system collects captured biometric data and a claimed identity and determines whether or not the captured biometric data matches the template stored for that identity. Although the term *authentication* is almost universally used in the information security industry for this operation, the term *verification* is often used by biometrics vendors and researchers to describe this.
- *Identification.* During this operation, a biometric system collects captured biometric data and attempts to find a match against any of the templates stored in a data storage subsystem.

Enrollment

Before a user can use a biometric system for either authentication or identification, a data storage subsystem needs to contain a template for the user. The process of initializing a biometric system with such a template is called *enrollment*, and it is the source of another error rate that can limit the usefulness of biometric systems. The interaction of the subsystems of a biometric system when enrolling a user is shown in Figure 56.13.

In the first step of enrollment, a user presents his biometric data to a data capture subsystem. The captured biometric data is then converted into a reference by a signal processing subsystem. This reference is then stored in a data storage subsystem, at which point it becomes a template. Such a template is typically calculated from several captures of biometric data to ensure that it reflects an accurate average value. An optional step includes using a matching subsystem to ensure that the user is not already enrolled.

The inherent nature of some captured biometric data as well as the randomness of captured biometric data can cause the enrollment process to fail. Some people have biometrics that are far enough outside the normal range of such data that they cause a signal processing subsystem to fail when it attempts to convert their captured data into a reference. The same types of random errors that contribute to the FMR and FNMR are also present in the enrollment process, and can be sometimes be enough to turn captured biometric data that would normally be within the range that the signal processing subsystem can handle into data that is outside this range. In some cases, it may even be impossible to collect some types of biometric data from some users, like the case where missing hands make it impossible to collect data on the geometry of the missing hands.

The probability of a user failing in the enrollment process is used to calculate the failure to enroll rate (FER). Almost any biometric can fail sometimes, either temporarily or permanently. Dry air or sticky fingers can cause fingerprints to temporarily change. A cold can cause a voice to temporarily become hoarse. A broken arm can temporarily change the way a person writes his signature. Cataracts can permanently make retina patterns impossible to capture. Some skin diseases can even permanently change fingerprints.

A useful biometric system should have a low FER, but because all such systems have a nonzero value for

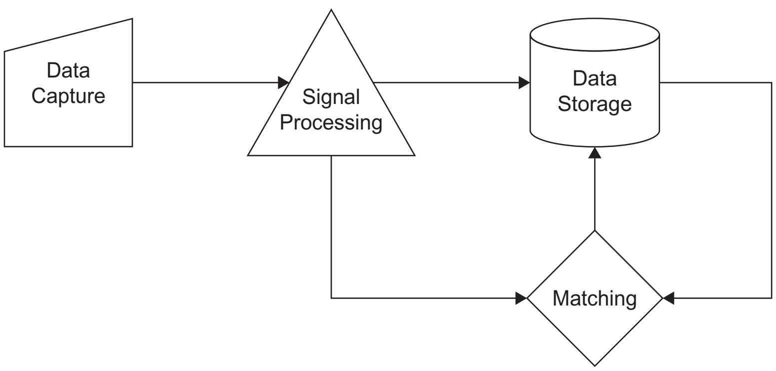

FIGURE 56.13 Enrollment in a biometric system.

this rate, it is likely that there will always be some users that cannot be enrolled in any particular biometric system, and a typical FER for a biometric system may be in the range of 1% to 5%. For this reason, biometric systems are often more useful as an additional means of authentication in multifactor authentication system instead of the single method used.

Authentication

After a user is enrolled in a biometric system, the system can be used to authenticate this user. The interaction of the subsystems of a biometric system when used to authenticate a user is shown in Figure 56.14.

To use a biometric system for authentication, a user first presents both a claimed identity and his biometric data to a data capture subsystem. The captured biometric data is then passed to a signal processing subsystem where features of the captured data are extracted and converted into a reference. A matching subsystem then compares this reference to a template from a data storage subsystem for the claimed identity and produces a comparison score. This comparison score is then passed to a decision subsystem, which produces a *yes* or *no* decision that reflects whether or not the biometric data agrees with the template stored for the claimed identity. The result of the authentication operation is the value returned by the decision subsystem.

A false match that occurs during authentication will allow one user to successfully authenticate as another user. So if Bob claims to be Alice and a false match occurs, he will be authenticated as Alice. A false nonmatch during authentication will incorrectly deny a user access. So if Bob attempts to authenticate as himself, he will be incorrectly denied assess if a false nonmatch occurs.

Because biometric data may change over time, an adaptation subsystem may update the stored template for a user after they have authenticated to the biometric system. If this is done, it will reduce the number or times that users will need to go through the enrollment process again when their biometric data changes enough to increase their FNMR rate to an unacceptable level.

Identification

A biometric system can be used to identify a user that has already enrolled in the system. The interaction of the subsystems of a biometric system when used for identification is shown in Figure 56.15.

To use a biometric system for identification, a user presents his biometric data to a data capture subsystem.

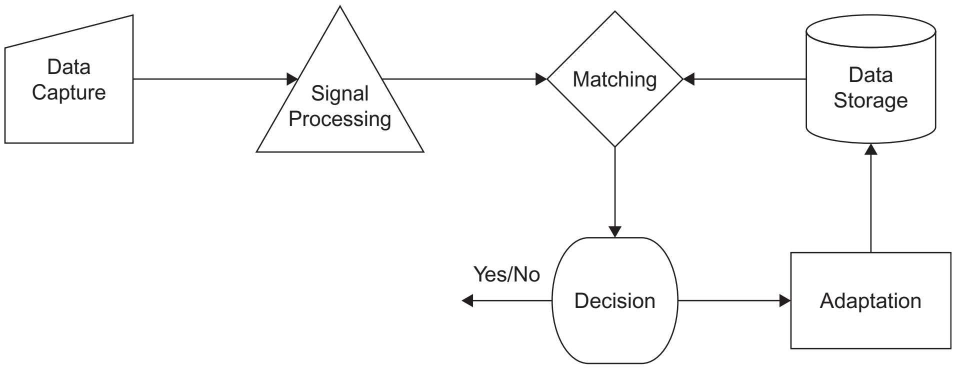

FIGURE 56.14 Authentication with a biometric system.

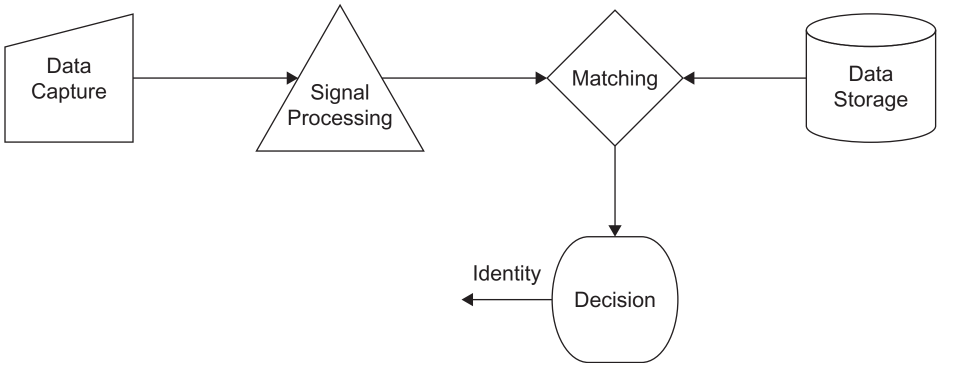

FIGURE 56.15 Identification with a biometric system.

The captured biometric data is then passed to a signal processing subsystem where features of the captured data are extracted and converted into a reference. A matching subsystem then compares this reference to each of the templates stored in a data storage subsystem and produces a comparison score. Each of these comparison scores are passed to a decision subsystem, which produces a *yes* or *no* decision that reflects whether or not the reference is a good match for each template. If a *yes* decision is reached, then the identity associated with the template is returned for the identification operation. It is possible for this process to return more that one identity. This may or may not be useful, depending on the application. If a *yes* decision is not reached for any of the templates in a data storage subsystem, then a response that indicates that no match was found is returned for the identification operation.

A false match that occurs during identification will incorrectly identify a user as another enrolled user. So if Bob uses a biometric system for identification, he might be incorrectly identified as Alice if a false match occurs. Because there are typically many comparisons done when a biometric system is used for identification, the FMR can increase dramatically because there is an opportunity for a false match with every comparison. Suppose that for a single comparison we have an FMR of ε_1 and that ε_n represents the FMR for n comparisons. These two error rates are related by $\varepsilon_n = 1 - (1 - \varepsilon_1)^n$. If $n \cdot \varepsilon_1 \ll 1$. then we have that $\varepsilon_n \approx n \cdot \varepsilon_1$. This means that for a small FMR, the FMR is increased by a factor equal to the number of enrolled users when a system is used for identification instead of authentication. So an FMR of 10^{-6} when a system is used for authentication will be increased to approximately 10^{-3} if the identification is done by comparing to 1000 templates. A false nonmatch during identification will fail to identify an enrolled user as one who is enrolled in the system. So Bob might be incorrectly rejected, even though he is actually an enrolled user.

4. SECURITY CONSIDERATIONS

Biometric systems differ from most other authentication or identification technologies in several ways, and these differences should be understood by anyone considering using such systems as part of an information security architecture. Biometric data is not secret, or at least it is not very secret. Fingerprints, for example, are not very secret because so-called latent fingerprints are left almost everywhere. On the other hand, reconstructing enough of a fingerprint from latent fingerprints to fool a biometric system is actually very difficult because latent fingerprints are typically of poor quality and incomplete. Because biometric data is not very secret, it may be useful to verify that captured biometric data is fresh instead of being replayed. There are technologies available that make it more difficult for an adversary to present fake biometric data to a biometric system for this very purpose. The technology exists to distinguish between a living finger and a manufactured copy, for example. Such technologies are not foolproof and can themselves be circumvented by clever attackers. This means that they just make it more difficult for an adversary to defeat a biometric system, but not impossible.

It is relatively easy to require users to frequently change their passwords and to enforce the expiration of cryptographic keys after their lifetime has passed, but many types of biometric data last for a long time, and it is essentially impossible to force users to change their biometric data. So when biometric data is compromised in some way, it is not possible to reissue new biometric data to the affected users. For that reason, it may be useful to both plan for alternate forms of authentication or identification in addition to a biometric system and to not rely on a single biometric system being useful for long periods of time.

Biometrics used for authentication may have much lower levels of security than other authentication technologies. This, plus the fact there is usually a non-zero FER for any biometric system, means that biometric systems may be more useful as an additional means of authentication than as a technology that can work alone. Types of authentication technology can be divided into three general categories or "factors":

- Something that a user *knows*, such as a password or PIN
- Something that a user *has*, such as a key or access card
- Something that a user *is* or *does*, which is exactly the definition of a biometric

To be considered a *multifactor* authentication system, a system must use means from more than one of these categories to authenticate a user so that a system that uses two independent password-based systems for authentication does not qualify as a multifactor authentication system, whereas one that uses a password plus a biometric does. There is a commonly held perception that multifactor authentication is inherently more secure than authentication based on only a single factor, but this is not true. The concepts of *strong* authentication, in which an attacker has a small chance of bypassing the means of authentication, and multifactor authentication are totally independent. It is possible to have strong authentication based on only one factor. It is also possible to have weak authentication based on multiple authentication factors. So, including a biometric system as part of a multifactor authentication system should be done for reasons other than to simply use more than a single authentication

factor. It may be more secure to use a password plus a PIN for authentication than to use a password plus a biometric, for example, even though both the password and PIN are the same type of authentication factor.

Error Rates

The usual understanding of biometric systems assumes that the FMR and FNMR of a biometric system are due to random errors that occur in a data capture subsystem. In particular, this assumes that the biometrics that are used in these systems are actually essentially unique. The existing market for celebrity lookalikes demonstrates that enough similarities exist in some physical features to justify the concern that similarities also exist in the more subtle characteristics that biometric systems use.

We assume, for example, that fingerprints are unique enough to identify a person without any ambiguity. This may indeed be true,[6] but there has been little careful research that demonstrates that this is actually the case. The largest empirical study of the uniqueness of fingerprints used only 50,000 fingerprints, a sample that could have come from as few as 5000 people, and has been criticized by experts for its careless use of statistics.[7] This is an area that deserves a closer look by researchers, but the expense of large-scale investigations probably means that they will probably never be carried out, leaving the uniqueness of biometrics an assumption that underlies the use of the technology for security applications. Note that other parts of information security also rely on assumptions that may never be proved. The security provided by all public-key cryptographic algorithms, for example, assumes that certain computational problems are intractable, but there are currently no proofs that this is actually the case.

The chances that the biometrics used in security systems will be found to be not unique enough for use in such systems is probably remote, but it certainly could happen. One easy way to prepare for this possibility is to use more than one biometric to characterize users. In such multi-modal systems, if one of the biometrics used is found to be weak, the others can still provide adequate strength. On the other hand, multi-modal systems have the additional drawback of being more expensive that a system that uses a single biometric.

Note that a given error rate can have many different sources. An error rate of 10% could be caused by an entire population having an error rate of 10%, or it could be caused by 90% of a population having an error rate of zero and 10% of the population having an error rate of 100%. The usability of the system is very different in each of these cases. In one case, all users are equally inconvenienced, but in the other case, some users are essentially unable to use the system at all. So understanding how errors are distributed can be important in understanding how biometric systems can be used. If a biometric system is used to control access to a sensitive facility, for example, it may not be very useful in this role if some of the people who need entry to the facility are unlucky enough to have a 100% FNMR. Studies have suggested that error rates are not uniformly distributed in some populations, but they are not quite as bad as the worst case. The nonuniform distribution of error rates that is observed in biometric systems is often called Doddington's Zoo and is named after the researcher who first noticed this phenomenon and the colorful names that he gave to the classes of users who made different contributions to the observed error rates.

Doddington's Zoo

Based on his experience testing biometric systems, George Doddington divided people into four categories: sheep, goats, lambs, and wolves.[8] Sheep are easily recognized by a biometric system and comprise most of the population. Goats are particularly unsuccessful at being recognized. They have chronically high FNMRs, usually because their biometric is outside the range that a particular system recognizes. Goats can be particularly troublesome if a biometric system is used for access control, where it is critical that all users be reliably accepted. Lambs are exceptionally vulnerable to impersonation, so they contribute to the FMR. Wolves are exceptionally good false matchers and they also make a significant contribution to the FMR.

Doddington's goats can also cause another problem. Because their biometric pattern is outside the range that a particular biometric system expects, they may be unable to enroll in such a system and thus be major contributors to the FER of the system.

Note that users that may be sheep for one biometric may turn out to be goats for another, and so on. Because of this it is probably impossible to know in advance how error rates are distributed for a particular biometric system, it is almost always necessary to test such systems thoroughly before deploying them on a wide scale.

Birthday Attacks

Suppose that we have n users enrolled in a biometric system. This biometric system maps arbitrary inputs into $n+1$ states that represent deciding on a match with one of the n users plus the additional "none of the above" user that represents the option of deciding on a match with none of the n enrolled users. From this point of view, this biometric system acts like a hash function so might try to use well-known facts about hash functions to understand the limits that this property puts on error rates. In particular, errors caused by the FMR of a biometric system look like a collision in this hash function, which happens when two different input values to a hash function result in the same output from the hash function. For this reason, we might think that the same "birthday attack" that can find collisions for a hash function can also increase the FMR of a biometric system. The reason for this is as follows.

For a hash function that maps inputs into m different message digests, the probability of finding at least one collision, a case where different inputs map to the same message digest, after calculating n message digests is approximately $1 - e^{-n^2/2m}$.[9] Considering birthdays as a hash function that maps people into one of 365 possible birthdays, this tells us that the probability of two or more people having the same birthday in a group of only 23 people is approximately $1 - e^{-23^2/2 \cdot 365} \approx 0.52$. This means that there is greater that a 50% chance of finding two people with the same birthday in a group of only 23 people, a result that is often counter to people's intuition. Using a biometric system is much like a hash function in that it maps biometric data into the templates in the data storage subsystem that it has a good match for, and collisions in this hash function cause a false match. Therefore, the FMR may increase as more users are added to the system, and if it does, we might expect the FMR rate to increase in the same way that the chances of a collision in a hash function do. This might cause false matches at a higher rate that we might expect, just like the chances of finding matching birthdays does.

In practice, however, this phenomenon is essentially not observed. This may be due to the nonuniform distribution in error rates of Doddingon's Zoo. If the threshold used in a decision subsystem is adjusted to create a particular FMR, it may be limited by the properties of Doddington's lambs. This may leave the sheep that comprise the majority of the user population with enough room to add additional users without getting too close to other sheep.

ANS X9.84 requires that the FMR for biometric systems provide at least the level of security provided by a four-digit PIN, which equates to an FMR of no greater than 10^{-4} and recommends that they provide an FMR of no more than 10^{-5}. In addition, this standard requires that the corresponding FNMR be no greater than 10^{-2} at the FMR selected for use. These error rates may be too ambitious for some existing technologies, but it is certainly possible to attain these error rates with some technologies.

TABLE 56.3 Comparison of Security Provided by Biometrics and Other Common Mechanisms.

FMR	PIN Length	Password Length	Key Length
10^{-3}	3 digits	2 letters	10 bits
10^{-4}	4 digits	3 letters	13 bits
10^{-5}	5 digits	4 letters	17 bits
10^{-6}	6 digits	4 letters	20 bits
10^{-7}	7 digits	5 letters	23 bits
10^{-8}	8 digits	6 letters	27 bits

On the other hand, these error rates compare very unfavorably with other authentication technologies. For example, an FMR of 10^{-4} is roughly the same as the probability of randomly guessing a four-digit PIN, a three-character password, or a 13-bit cryptographic key. And although few people would find three-character passwords or 13-bit cryptographic keys acceptable, they might have to accept an FMR of 10^{-4} from a biometric system because of the limitations of affordable current technologies. Table 56.3 summarizes how the security provided by various FMRs compares to both the security provided by all-numeric PINs and passwords that use only case-independent letters.

Comparing Technologies

There are many different biometrics that are used in currently available biometric systems. Each of these competing technologies tries to be better than the alternatives in some way, perhaps being easier to use, more accurate, or cheaper to operate. Because there are so many technologies available, however, it should come as no surprise that there is no single "best" technology for use in biometric systems. Almost any biometric system that is available is probably the best solution for some problem, and it is impossible to list all of the cases where each technology is the best without a very careful analysis of each authentication or identification problem. So any attempt to make a simple comparison between the competing technologies will be inherently inaccurate. Despite this, Table 56.4 attempts to make such a high-level

9. D. Knuth, *The Art of Computer Programming*, *Volume 2: Sorting and Searching*, Addison-Wesley, 1973.

TABLE 56.4 Comparison of Selected Biometric Technologies.

Biometric	Ease of Use	Accuracy	Cost
DNA	Low	High	High
Face geometry	High	Medium	Medium
Fingerprint	High	High	Low
Hand geometry	Medium	Medium	Medium
Iris	High	High	High
Retina	Medium	High	High
Signature dynamics	Low	Medium	Medium
Voice	Medium	Low	Low
(Password)	(Medium)	(Low)	(Low)

comparison. In this table, the ease of use, accuracy and cost are rated as high, medium, or low.

Using DNA as a biometric provides an example of the difficulty involved in making such a rough classification. The accuracy of DNA testing is limited by the fairly large number of identical twins that are present in the overall population, but in cases other than distinguishing identical twins it is very accurate. So if identical twins need to be distinguished, it may not be the best solution. By slightly abusing the usual understanding of what a biometric is, it is even possible to think of passwords as a biometric that is based purely on behavioral characteristics, along with the FMR, FNMR, and FER rates that come with their use, but they are certainly outside the commonly understood meaning of the term. Even if they are not covered by the usual definition of a biometric, passwords are fairly well understood, so they provide a point of reference for comparing against the relative strengths of biometrics that are commonly used in security systems. The accuracy of passwords here is meant to be that of passwords that users select for their own use instead of being randomly generated. Such passwords are typically much weaker than their length indicates because of the structure that people need to make passwords easy to remember. This means that the chances of guessing a typical eight-character case-insensitive password is actually much greater than the 26^{-8} that we would expect for strong passwords. Studies of the randomness in English words have estimated that there is approximately one bit of randomness per letter.[10] If we conservatively double this to estimate that there are approximately two bits of randomness per letter in a typical user-selected password, we get the estimate that an eight-character password probably provides only about 16 bits of randomness, which is close to the security provided by a biometric system with an FMR of 10^{-5}. This means that the security of passwords as used in practice is often probably comparable to that attainable by biometric systems, perhaps even less if weak passwords are used.

10. C. Shannon, "Prediction and entropy of printed english," *Bell System Technical Journal*, Vol. 30, pp. 50–64, January 1951.

Storage of Templates

One obvious way to store the templates used in a biometric system is in a database. This can be a good solution, and the security provided by the database may be adequate to protect the templates that it stores. In other cases, it may be more useful for a user to carry his template with him on some sort of portable data storage device and to provide that template to a matching subsystem along with his biometric data. Portable, credit-card-sized data storage devices are often used for this purpose. There are three general types of such cards that are used in this way, and each has a different set of security considerations that are relevant to it.

In one case, a memory card with unencrypted data storage can be used to store a template. This is the least expensive option, but also the least secure. Such a memory card can be read by anyone who finds it and can easily be duplicated, although it may be impossible for anyone other that the authorized user to use it. Nonbiometric data stored on such a card may also be compromised when a card is lost.

In principle, a nonauthorized user can use such a card to make a card that lets them authenticate as an authorized user. This can be done as follows. Suppose that Eve, a nonauthorized user, gets the memory card that stores the template for the authorized user Alice. Eve may be able to use Alice's card to make a card that is identical in every way to Alice's card but that has Eve's template in place of Alice's. Then when Eve uses this card to authenticate, she uses her biometric data, which then gets compared to her template on the card and gets her authenticated as the user Alice. Note that doing this relies on a fairly unsecured implementation.

A case that is more secure and also more expensive is a memory card in which data storage is encrypted. The contents of such a card can still be read by anyone who finds it and can easily be duplicated, but it is infeasible for an unauthorized user to decrypt and use the data on the card, which may also include any nonbiometric data on the card. Encrypting the data storage also makes it impractical for an unauthorized user to make a card that will let them authenticate as an authorized user. Though it may be possible to simply replace one template with another if the template is stored unencrypted on a

memory card, carrying out the same attack on a memory card that stores data encrypted requires being able to create a valid encrypted template, which is just as difficult as defeating the encryption.

The most secure as well as the most expensive case is where a smart card with cryptographic capabilities is used to store a template. The data stored on such a smart card can only be read and decrypted by trusted applications, so that it is infeasible for anyone who finds a lost smart card to read data from it or to copy it. This makes it infeasible for unauthorized users to use a smart card to create a way to authenticate as an authorized user. It also protects any nonbiometric data that might be stored on the card.

5. SUMMARY

Using biometric systems as the basis for security technologies for authentication or identification is currently feasible. Each biometric has properties that may make it useful in some situations but not others, and security systems based on biometrics have the same property. This means that there is no single “best” biometric for such use and that each biometric technology has an application where it is superior to the alternatives.

There is still a great deal of research that needs to be done in the field, but existing technologies have progressed to the point that security systems based on biometrics are now a viable way to perform authentication or identification of users, although the properties of biometrics also make them more attractive as part of a multifactor authentication system instead of the single means that is used.

Finally, let’s move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor’s Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? *Biometrics* is the analysis of biological observations and phenomena. People routinely use biometrics to recognize other people, commonly using the shape of a face or the sound of a voice to do so.
2. True or False? Not all biometric systems have a number of common subsystems.
3. True or False? A data subsystem collects captured biometric data from a user.
4. True or False? A signal processing subsystem takes the captured biometric data from a data subsystem and transforms the data into a form suitable for use in the matching subsystem.
5. True or False? A matching subsystem receives a reference from a signal processing subsystem and then compares a template from a data storage subsystem.

Multiple Choice

1. What subsystem stores templates that are used by the matching subsystem?
   A. Qualitative analysis
   B. Vulnerabilities
   C. Data storage
   D. Malformed request DoS
   E. Data controller
2. What subsystem takes a comparison score that is the output of a matching subsystem and returns a binary *yes* or *no* decision from it?
   A. Network attached storage (NAS)
   B. Risk assessment
   C. Valid
   D. Decision
   E. Bait
3. One way to avoid the potential difficulties associated with having users eventually becoming unrecognizable is to update their template after a successful authentication. This process is called:
   A. Adaptation
   B. Fabric
   C. Disasters
   D. Risk communication
   E. Security
4. During what operation, does a biometric system create a template that is used in later authentication and identification operations?
   A. Enrollment
   B. Greedy strategy
   C. Infrastructure failure
   D. SAN protocol
   E. Taps
5. During what operation, does a biometric system collect captured biometric data and a claimed identity and determines whether or not the captured biometric data matches the template stored for that identity?
   A. Irrelevant
   B. Authentication
   C. IP storage access
   D. Configuration file
   E. Unusable

1. ABSTRACT

The September 11, 2001, terrorist attacks, permanently changed the way the United States and the world's other most developed countries perceived the threat from terrorism. Massive amounts of resources were mobilized in a very short time to counter the perceived and actual threats from terrorists and terrorist organizations. In the United States, this refocus was pushed as a necessity for what was called *homeland security*. The homeland security threats were anticipated for the IT infrastructure as well. It was expected that not only the IT at the federal level was vulnerable to disruptions due to terrorism-related attacks but, due to the ubiquity of the availability of IT, any organization was vulnerable. Soon after the terrorist attacks, the U.S. Congress passed various new laws and enhanced some existing ones that introduced sweeping changes to homeland security provisions and to the existing security organizations. The executive branch of the government also issued a series of Homeland Security Presidential Directives to maintain domestic security. These laws and directives are comprehensive and contain detailed provisions to make the U.S. secure from its vulnerabilities. Later in the chapter, we describe some principle provisions of these homeland security-related laws and presidential directives. Next, we discuss the organizational changes that were initiated to support homeland security in the United States. Then we highlight the 9-11 Commission that Congress charted to provide a full account of the circumstances surrounding the attacks and to develop recommendations for corrective measures that could be taken to prevent future acts of terrorism. We also detail the Intelligence Reform and Terrorism Prevention Act of 2004 and the Implementing the 9-11 Commission Recommendations Act of 2007. Finally, we summarize the chapter's discussion.

Cyber Warfare

Anna Granova
Pretoria Society of Advocates

Marco Slaviero
SensePost Pty Ltd

The times we live in are called the Information Age for very good reasons: Today information is probably worth much more than any other commodity. Globalization, the other important phenomenon of the times we live in, has taken the value of information to new heights. On one hand, citizens of a country may now feel entitled to know exactly what is happening in other countries around the globe. On the other, the same people can use the Internet to mobilize forces to overthrow the government in their own country.[1] To this end, the capabilities of the Internet have been put to use and people have become accustomed to receiving information about everyone and everything as soon as it becomes available. The purpose of this chapter is to define the concept of cyber warfare (CW), discuss their most common tactics, weapons, and tools, compare CW terrorism with conventional warfare, and address the issues of liability and the available legal remedies under international law. To have this discussion, a proper model and definition of CW first needs to be established.

October 20, 1969, marked the first message sent on the Internet,[2] and more 40 years on we cannot imagine our lives without it. Internet banking, online gaming, and online shopping and social media have become just as important to some as food and sleep. As the world has become more dependent on automated environments, interconnectivity, networks, and the Internet, instances of abuse and misuse of information technology infrastructures have increased proportionately.[3] Such abuse has, unfortunately, not been limited only to the abuse of business information systems and Web sites but over time has also penetrated the military domain of state security. Today this penetration of governmental IT infrastructures, including, among others, the military domain, is commonly referred to as *cyber warfare*. However, these concepts are not yet clearly defined and understood. Furthermore, this type of warfare is a multidisciplinary field requiring expertise from technical, legal, offensive, and defensive perspectives. Information security professionals are challenged to respond to this type of warfare issues in a professional and knowledgeable way.

1. CYBER WARFARE MODEL

The authors propose a model for CW by mapping important concepts regarding them on a single diagrammatic representation (see Figure 58.1). This aids in simplifying a complex concept as well as providing a holistic view on the phenomenon. To this end, this chapter addresses the

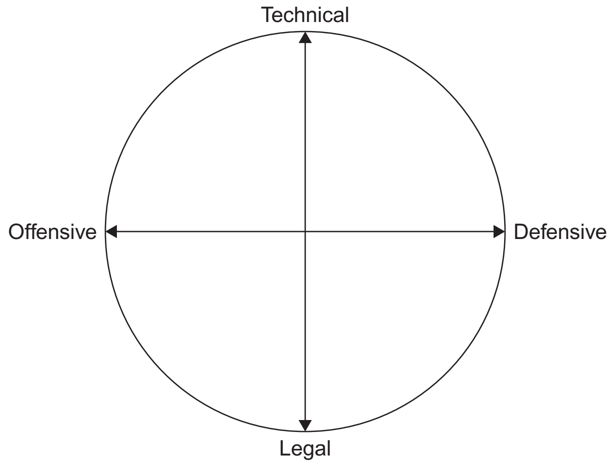

FIGURE 58.1 A perspective on CW.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00058-1

four axes of CW: technical, legal, offensive, and defensive, as depicted in Figure 58.1.

The technical side of CW deals with technical exploits on one side and defensive measures on the other. As is apparent from Figure 58.1, these range from the most destructive offensive strategies, such as a distributed denial-of-service (DDoS) attack or stuxnet, to various workstation emergency response teams, such as US-CERT.

Considered from a legal perspective, CW can range from criminal prosecutions in international courts to use of force in retaliation. Therefore, the four axes of CW continuously interact and influence each other, as will become clearer from the discussion that follows.

2. CYBER WARFARE DEFINED

The manner in which war is being conducted has evolved enormously,[4] and CW has not only been accepted as a new direction in military operations,[5] but also been incorporated into some of the top military forces in the world, with China implementing an CW policy as early as 1995,[6] with United States Cyber Command (USCYBERCOM) established in 2009,[7] followed by China in July 2010,[8] US Cyber Warfare Intelligence Center[9] unveiled in November 2010 and the Cyber Warfare Administration in Israel in breathed into life in 2012.[10] A number of definitions are relevant for the purposes of this chapter. Some authors[11] maintain that CW covers "the full range of competitive information operations from destroying IT equipment to subtle perception management, and from industrial espionage to marketing." If one regards the more "military" definition of CW, one could say that CW is "a subset of information operations"—in other words "actions taken to adversely affect information and information systems while defending one's own information and information systems."[12]

The UN Secretary-General's report on *Development in the Field on Information and Telecommunications in the context of International Security* describes CW as "actions aimed at achieving information superiority by executing measures to exploit, corrupt, destroy, destabilise, or damage the enemy's information and its functions."[13] This definition is very similar to one of the more recent and accepted definitions found in literature that states that CW is "actions taken in support of objectives that influence decision-makers by affecting the information and/or information systems of others while protecting your own information and/or information systems."[14] If one, however, looks at CW in purely a military light, the following technical definition seems to be the most appropriate: "The broad class of activities aimed at leveraging data, information and knowledge in support of military goals."[15]

In light of the preceding, it is clear that CW is all about information superiority because "the fundamental weapon and target of CW is information."[16] This being so, some authors[17] outline the basic strategies of CW as follows:

1. Deny access to information
2. Disrupt/destroy data
3. Steal data
4. Manipulate data to change its context or its perception

A slightly different perspective on the aims of CW is perhaps to see it as "an attack on information systems for military advantage using tactics of destruction, denial, exploitation or deception."[18] Since about 2008, however, the CW starting to cross over into the physical realm through one of its forms: cyber warfare, which can be defined as "*politically motivated hacking to conduct sabotage and espionage*".

With these definitions in mind, it is now appropriate to consider whether CW is a concept that has been created by enthusiasts such as individual hackers to impress the rest of the world's population or is, in fact, part of daily military operations.

3. CW: MYTH OR REALITY?

Groves once said: ". . . nowhere it is safe . . . no one knows of the scale of the threat, the silent deadly menace that stalks the network."[19] With the growing risk of terrorists and other hostile entities engaging in missions of sabotaging, either temporarily or permanently, important public infrastructures through cyber attacks, the number of articles[20] on the topic has grown significantly. To understand the gravity of CW and its consequences, the following real-life examples need to be considered. At the outset, however, it is important to mention that the reason there is so little regulation (see checklist, "An Agenda For Action For Regulating High Level Cyber Warfare Strategies") of computer-related activities with specific reference to CW both on national and international planes is that lawyers are very reluctant to venture into the unknown. The following examples, however, demonstrate that CW has consistently taken place since at least 1991. One of the first CW incidents was recorded in 1991 during the first Gulf War, where CW was used by the United States against Iraq.[21]

In 1998 an Israeli national hacked into the government workstations of the United States.[22] In 1999, a number of cyber attacks took place in Kosovo. During the attacks the Serbian and NATO Web sites were taken down with the aim of interfering with and indirectly influencing the public's perception and opinion of the conflict.[23]

These cyber attacks were executed for different reasons: Russians hacked U.S. and Canadian websites "in protest" against NATO deployment,[24] Chinese joined the online war because their embassy in Belgrade was bombed by NATO,[25] and U.S. nationals were paralyzing the White House[26] and NATO[27] Web sites "for fun." In 2000, classified information was distributed on the Internet,[28] and attacks were launched on NASA's laboratories,[29] the U.S. Postal Service, and the Canadian Defense Department.[30] As early as 2001, detected intrusions into the U.S. Defense Department's Web site numbered 23,662.[31] Furthermore, there were 1300 pending investigations into activities "ranging from criminal activity to national security intrusions."[32] Hackers also attempted to abuse the U.S. Federal Court's database[33] to compromise the peace process in the Middle East.[34]

In 2002, incidents of cyber terrorism in Morocco, Spain, Moldova, and Georgia[35] proved once again that a "hacker influenced by politics is a terrorist," illustrated by more than 140,000 attacks in less than 48 hours allegedly executed by the "G-Force" (Pakistan)[36] . During this period, a series of convictions on charges of conspiracy, the destruction of energy facilities,[37] the destruction of telecommunications facilities, and the disabling of air navigation facilities,[38] as well as cases of successful international luring and subsequent prosecutions, were recorded.[39]

In the second half of 2007, 499,811 new malicious code threats were detected, which represented a 571% increase from the same period in 2006.[40] With two thirds

An Agenda for Action for Regulating High Level Cyber Warfare Strategies

Please see the following recommendations for regulating high level cyber warfare strategies (Check All Tasks Completed):

_____**1.** The President of the United States should task the National Office for Cyberspace (NOC) to work with appropriate regulatory agencies to develop and issue standards and guidance for securing critical cyber infrastructure, which those agencies would then apply in their own regulations.

_____**2.** The NOC should work with the appropriate regulatory agencies and with the National Institute of Standards and Technology (NIST) to develop regulations for industrial control systems (ICS).

_____**3.** The government should reinforce regulations by making the development of secure control systems an element of any economic stimulus package.

_____**4.** The NOC should immediately determine the extent to which government-owned critical infrastructures are secure from cyber attack.

_____**5.** The president should direct the NOC and the federal Chief Information Officers Council, working with industry, to develop and implement security guidelines for the procurement of IT products (with software as the first priority).

_____**6.** The president should task the National Security Agency (NSA) and NIST, working with international partners, to reform the National Information Assurance Partnership (NIAP).

_____**7.** The president should take steps to increase the use of secure Internet protocols.

_____**8.** The president should direct the Office of Management OMB and the NOC to develop mandatory requirements for agencies to contract only with telecommunications carriers that use secure Internet protocols.

of more than 1 million identified viruses created in 2007,[41] the continued increase in malicious code threats has been linked to the sharp rise in the development of new Trojans and the apparent existence of institutions that employ "professionals" dedicated to creation of new threats.[42] In 2008 it has been reported in the media that "over the past year to 18 months, there has been 'a huge increase in focused attacks on our [United States] national infrastructure networks .... and they have been coming from outside the United States.'"[43]

It is common knowledge that over the past 15 years, the United States has tried to save both manpower and costs by establishing a system to remotely control and monitor the electric utilities, pipelines, railroads, and oil companies all across the United States.[44] The reality of the threat of CW has been officially confirmed by the U.S. Federal Energy Regulatory Commission, which approved eight cyber-security standards for electric utilities, which include "identity controls, training, security 'parameters' physical security of critical cyber equipment, incident reporting and recovery."[45] In January 2008, a CIA analyst warned the public that cyber attackers have hacked into the workstation systems of utility companies outside the United States and made demands, which led to at least one instance where, as a direct result, a power outage that affected multiple cities took place.[46]

Furthermore, since 2007, there have been a number of high profile events, which can be categorized as cyber attacks. Estonia was first in line to suffer from this debilitating form of aggression: it unleashed a wave of DdoS attacks, where websites were swamped by tens of thousands of requests, which in turn disabled them by overcrowding the bandwidths for the servers running the websites of the Estonian government, political parties, half of media organizations and the top two banks.[47]

Russia was blamed for the Estonian cyber conflict which was caused by the removal of a statue of

significant importance to Russian people. The repeat of the showdown, but now with Georgia on the receiving end, was witnessed in 2008 when Georgia was literally blown offline during its military conflict with Russia.[48]

China also appears to be waging a persistent low-profile campaign against many foreign nations, such as Japan,[49] the United States[50] and the United Kingdom.[51] The United States themselves are not above suspicion: some experts hint that it might have been that country[52] that unleashed such a powerful "cyber weapon" as Stuxnet which impacted Iran's ability to conduct nuclear research.

With Duqu worm having been discovered on 01 September 2011, and showing similar capabilities as Stuxnet,[53] it is only a matter of time before one is able to find the country behind the worm by analyzing the motives behind the facility which will suffer its onslaught. The appropriate questions that then arise are: How can CW be brought about and how can one ward against it?

4. CYBER WARFARE: MAKING CW POSSIBLE

To conduct any form of warfare, one would require an arsenal of weapons combined with an array of defensive technologies as well as laboratories and factories for researching and producing both. As far as CW is concerned, three general strategies need to be considered: preparation, offensive strategies and defensive strategies.

Preparation

Without arms, wars cannot be fought. Weapons are not constructed overnight and so in order to be prepared to enter any war, a state must have stockpiles of weapons ready to be deployed; CW is no different. Preparation will play a major role in CW as hostile acts occur in seconds or minutes, but the acts themselves are the culmination of many man-years worth of work.

In addition to training personnel and producing cyber weapons, the preparation stage also consists of a wide range of information gathering activities. Effective warfare is premised on knowledge of the opponent's weaknesses, and having extensive knowledge of an adversary's technology and networks prior to any hostilities is important for planning.

Preparation thus broadly consists of research, reconnaissance and vulnerability enumeration. The preparation phase never reaches a conclusion; ongoing research produces new tools, vulnerabilities and exploits, reconnaissance must continually discover new targets while removing stale targets, and vulnerability enumeration must keep track of new and old targets, while testing for recent vulnerabilities.

Research

CW does not require the infrastructure investment that physical arms do,[54] however it requires highly trained personnel to develop cyber weapons and the process of training to the required skill levels occupies a significant portion of activities prior to hostilities breaking out. In addition, once personnel have the necessary skills they need time to uncover vulnerabilities and turn those into usable weapons. These are separate jobs; the notion of vulnerability research as a separate discipline to exploit writing is growing especially as the continued fragmentation of applications and hardware forces extreme specialization. In the commercial information security market, vulnerability research and exploit writing are often separate tasks handed to different individuals, especially where memory corruption bugs are concerned.

The bug finders' skills tend towards quickly understanding how an application or system is built, how they often fail using common usage patterns and the ability to reverse engineer protocols quickly. Good bug finders are adept at automating this process. Their task, for example,

is to find input that will cause a memory corruption to occur, after which the test case is handed to an exploit writer. Vulnerabilities are found at all layers and are introduced all stages of development, and vulnerability research strives to understand each component. Software bugs are not the only target; flaws in algorithms are highly valued and common misconfigurations often yield trivial exploits.

The exploit writer has extreme specialist knowledge of the inner working of the operating system on which the application runs, and is able to craft exploits that bypass operating system protections designed to thwart their exploits. With a working exploit in hand, the exploit writer then ensures it runs without crashing across a wide range of possible versions of the target software and operating system. The exploit will also often be obfuscated in some manner, to avoid detection. For the moment it serves to simplify cyber arms by thinking of them as exploits, but as we shall see, cyber weapons consist of further components.

The combined process of finding a bug and writing an exploit for it can take months. While not all vulnerabilities require that level of input, it is by no means extreme. Consider that cyber weapons are not simply just bugs and exploits; superficially, configuration and operational failures are prevalent but deeper issues in protocols and algorithms also exist.

Reconnaissance

This phase of preparation focuses on identifying government organs, industries, infrastructure, companies, organizations and individuals that are potential targets. This is fed by a country's intelligence services, and overlaps with targets for physical warfare. In producing targets, information is gathered on the purpose of the targets, likely data that they store, technologies in use, network presence (on public or private networks) and channels by which the target could be engaged.

A discovery exercise is conducted on targets to determine which network services, if any, are accessible. Access to targets over the Internet is certainly not a requirement for CW but, for those that are, prior knowledge of their presence saves time when hostilities break out.

Vulnerability Enumeration

With reconnaissance complete, the next preparation step is to discover vulnerable systems. Vulnerability scanning is a common activity in the commercial security industry, and numerous scanners exist. A scanner has a large database holding knowledge of tens of thousands of issues, as well as how to test for those issues. The kinds of tests vary; in some instances a test consists of simply checking a software version number extracted from a service banner, but in other tests more complex methods are required such as harmless exploits that confirm the vulnerability but do not take further action. By unleashing the scanner on a wide range of targets, a database of vulnerable machines can be saved prior to an CW.

Vulnerable systems are not the only benefit of wide scale scanning. Even a database of version numbers or technology types will improve targeting, for example when vulnerabilities for a system are discovered in the future.

The problem with scanners is that they are not subtle. They often test for issues unrelated to the technology on which the service runs, and protection mechanisms such as IDS are tuned to detect vulnerability scans. One improvement is scanning for specific issues across the target's networks which reduces the likelihood of detection, as well as masking tests to evade signature-based detection methods.

Offensive Strategies

Scale is an important decision in deciding on an CW strategy. To extend the analogy of physical warfare, the strategic focus in CW could either be on small but highly experienced and trained tactical teams who are able to compromise targets at will, or to deploy an overwhelming number of moderately skilled operators. The analogy has flaws: whereas adding an extra operator in the physical realm increases the capabilities of that unit, adding extra CW operators past some point starts to see diminishing returns. The reason for this is that many CW operations can be automated and parallelized; additional *infrastructure* is often more valuable than additional personnel. Smaller teams decrease personnel and training costs, though they are more vulnerable to physical attacks against the teams.

A second consideration is the type of hostilities that CW covers. It will very likely be employed as a support to a kinetic war in the same way that ground troops value air cover. There is a second set of tactics that are *covert*, and these are akin to espionage. Regardless of whether the strategy is overt or covert, we refer to them a hostilities.

The arsenal of CW includes weapons of psychological and technical nature. Both are significant and a combination of the two can bring about astounding and highly disruptive results.

Psychological Weapons

Psychological weapons include social engineering techniques and psychological operations *(psyops).* Psyops

include deceptive strategies, which have been part of warfare in general for hundreds of years.

Sun Tzu, in his fundamental work on warfare, says that "All warfare is based on deception."[55] Deception has been described as "a contrast and rational effort ... to mislead an opponent."[56] In December 2005, it became known that the Pentagon was planning to launch a US $300 million operation to place pro-U.S. messages "in foreign media and on items such as T-shirts and bumper stickers without disclosing the U.S. government as the source."[57]

Trust is a central concept and a prerequisite for any psyops to succeed. Traditionally, trust was vested in institutions and roles; a stranger in uniform might be afforded recognition based on the trust (if any) one has in the organization they are representing, without knowing them personally. Computer networks have, for some time now, been attacked by so-called "Social Engineers" who excel in gaining and exploiting trust, and cybercrime activities such as phishing rely on victims associating mere graphics on a website with the trust they invest in their bank.

However, this does not represent an exhaustive list of psyops. Psyops can also target the general population by substituting the information on well-trusted news agencies' Web sites as well as public government sites with information favorable to the attackers. A good example is where the information on the Internet is misleading and does not reflect the actual situation on the ground.

Today, social networks are highly efficient tools for spreading information. The instantaneous broadcast nature of micro-blogging sites such as Twitter mean that consumers rely more on social tools for obtaining information about current events than traditional media. In the heat of the moment, fact-checking quality decreases and the probability of inserting false information into social platforms increases. Social networks are also useful in guiding public conversations; Russia's legislative elections of 2011 saw automated software posting thousands of messages on Twitter in order to drown out opposition.[58]

The problem with psyops is that they cannot be used in isolation because once the enemy stops trusting the information it receives and disregards the bogus messages posted for its attention, psyops become useless, at least for some time. Therefore, technical measures of CW should also be employed to achieve the desired effect, such as DoS and botnet attacks. That way, the enemy might not only be deceived but the information the enemy holds can be destroyed, denied, or even exploited.

Technical Weapons

There are non-subtle differences between weapons that exist in the physical realm and those that exist within the cyber realm, and the differences are useful to highlight. Bluntly put, there is no patch for an Intercontinental Ballistic Missile. To refine this further, a significant challenge facing a cyber army is that, while their attacks can occur virtually instantly, the target is able to respond as rapidly. The response may be to rollout patches for known issues, develop new patches for new vulnerabilities, employ perimeter defenses to filter out the attack traffic or simply disconnect the targeted system or network (perhaps, in the worst case scenario, even disconnect a country.)

A further challenge is the carrying of CW traffic. In the physical world, air and water provide the channels by which weapons are deployed, but in the cyber realm the path between two points is governed by a very different geography. It is a truism that in order to attack a network, an access channel extending from the attacker to the target is required. It could be a disconnected channel using flashdrives, or a highly technical and difficult operation such as the conquest of military satellites with ground-based resources or breaking into submarine cables, but the attacker must have a viable means for delivering their attack. While these complex or unreliable channels are possible, a more likely carrier for CW traffic is commercial Internet infrastructure supplied and maintained by global Internet Service Providers (ISPs), as they provide publicly accessible network links between countries around the world. In relying on commercial ISPs, attackers have the benefit of plausible deniability on the one hand, and on the other the ability to extend their reach into the commercial space of the target country, before attacking government and military targets.

CW attacks have the advantage that their implementation can be deployed long before any declaration of war. Whereas it is difficult to deploy physical armaments in preparation for detonating them near a target prior to a declaration of war, cyber attacks do not have the same limitation. Preparing attack launch pads either by compromising systems or by renting data center space can be performed months if not years in advance of attacks. When CW commences, the attacker is already well placed to wreak damage. A particularly effective force will compromise their target's supply chain, infusing equipment with backdoors years before they are used.

Rules of engagement present a further challenge. Traditional weapons are deployed at predetermined points in a conflict: artillery is seldom deployed when friendly

troops are in the vicinity of the target, nuclear weapons may be a disproportionate response to a minor border skirmish and attacking schools or hospital without authorization may lie outside of a force's rules of engagement. Each armament has known side effects and its impact can be predicted; a commander in a physical war will understand which weapons are appropriate in each circumstance and deploy those that achieve their objectives while remaining within the constraints that are their policies and procedures. However, these norms have not been established publicly for CW, where *appropriate response* has yet to be defined. The dynamic nature of CW also means that, regardless of tools and techniques developed in the preparation phase, tools will be rapidly written during hostilities in reaction to new information or circumstances, and these could be trialed in the field while a conflict is active. Without perfect knowledge of exactly what a system controls or influences, unexpected consequences will be common in CW as the effects of an attack cannot be completely predicted.

The final significant difference between CW weapons and physical armaments is that their deterrence value is markedly different. Physical weapons demonstrate capability, which a cautious enemy will note. Developing defenses and counter-attacks against new weapons takes time in the real world, and so publicly exposing weapons capabilities can serve to avoid conflict. In the digital realm however, revealing one's weapons to an opponent simply highlights the areas they need to monitor, patch or upgrade. If an opponent provides evidence of working exploits against SoftwareX then, as a first line of defense, all of the target's machines running SoftwareX are moved behind additional layers and a plan is formulated to migrate away from SoftwareX. The defense can also perform their own investigation into SoftwareX, to determine the possible bug. By the time a conflict occurs, the revealed weapons are no longer useful. It has been shown in the commercial software exploit market that merely publishing seemingly innocuous descriptions of bugs can lead to experienced bug finders rapidly repeating the discovery without additional help. Demonstrating cyber capabilities is a confidence game in which a little skin is shown, in order to imply the strength of weapons that remain hidden. This is very susceptible to bluffing and subterfuge. With all this in mind, what do cyber weapons look like?

Previous work defined them as individual tools such as viruses, Trojans and so on. However, CW is fought at a larger scale than individual attacks, exploits and vulnerabilities. A commander on an CW battlefield is concerned with achieving objects such as disabling powergrids to support a kinetic attack on a facility. The commander firstly requires a team and infrastructure that is able to communicate and act in a distributed fashion; channeling attacks across lone routes or network links exposes a single point of failure, and attacks should be launched from a platform that is close in network terms to the target. This platform may be some distance from the command post. The weapons should be capable of working across multiple locations, and the payloads too must run in parallel and from multiple points in the network. Secondly, the commander must remain in control of attacks. For example, a worm that is unleashed against a target cannot indiscriminately attack targets on the public Internet as this would not help achieve the goal, and possibly result in collateral damage of systems unrelated to the opponent. Attacks would either be directly controlled by the commander through a command channel, or the attack would be self-limiting in terms of time or through built-in target detection. Examples of target detection are hardcoded addresses (when the reconnaissance phase was effective,) or a set of heuristics for determining at run-time whether a potential target should be attacked. This was seen in the Stuxnet attack, where the malicious code contained numerous heuristics to determine when it had finally migrated to the target SCADA installation. Until those heuristics were triggered, the program did nothing except attempt to migrate further. Lastly, a feedback loop that keeps the commander updated on whether the attack has succeeded is important. If the attack has a physical effect (for example, knocking out a powergrid), then the feedback loop would include forces on the ground. However, where the impact is virtual, then detecting attack success is not so clear cut. Consider the objective of disabling an opponent's logistics capability by preventing access to their logistics application through a deluge of traffic. Should the application become unresponsive from an attacker's perspective then it is not immediately apparent if the cause of the outage was a successful attack or due to the attack being detected and all the attacker's traffic blocked. Telemetry is vitally important.

Remember that CW is an "attack on information systems for military advantage using tactics of destruction, denial, exploitation or deception." The tactics by which the advantage is gained are determined by the weaknesses in the opponents systems, not the weapons in one's arsenal. This is important as it suggests that CW is not defined simply in terms of a set of tools; rather, the purpose or intent behind the deployment of a tactic is what defines a tactic to be part of an CW action. We shall see that so-called cyber weapons, in many circumstances, are called viruses, Trojans and the like when deployed by criminals or fraudsters. In that sense, the actual malicious components are less interesting as they are seldom unique to the field of CW and have been covered in this book already. The broader set of CW tools includes vulnerability databases, deployment tools, payloads and control consoles.

Vulnerability Databases

The vulnerability database is the result of an effort to collect information about all known security flaws in software. From the outset, it is obvious this is a massive challenge as vulnerability information is generated by thousands of sources including software vendors, vulnerability researchers and users of the software. Public efforts exist to provide identifiers for security weaknesses in software applications, such as the MITRE Corporations' Common Vulnerabilities and Exposures (CVE) project, which defines itself as "dictionary of common names (CVE Identifiers) for publicly known information security vulnerabilities."[59] The CVE contains information about a particular vulnerability in a software product, but for CW this is only part of the required information. A truly useful CW vulnerability database will also include those opposing systems that have been discovered to exhibit a particular weakness. The weaknesses are not simply software vulnerabilities; in many cases misconfigurations lead to compromise, and these are not problems with the code but snags resulting from the manner in which the system was setup.

Deployment Tools

Commonly seen in commercial malware where they are known as "droppers", deployment techniques are a separate beast from the payload that executes after compromise. Deployment occurs by exploiting a vulnerability, attacking a misconfiguration, spreading misinformation, spoofing communications, collusion or coercion. Stuxnet, for example, was deployed via four previously unknown vulnerabilities in Microsoft Windows, as well as through known network-based attacks. What made Stuxnet particularly interesting is that one infection mechanism was via USB flashdisks, as the target was presumed to not have public Internet connectivity.

Development of deployment tools occupies a large portion of the preparation phase, as discovered vulnerabilities and their exploits written form the basis for deploying malicious code. A stockpile of these tools aids an CW action, especially where tools take advantage of unknown flaws in software (termed "zero day", "0day", "0-day" or "oh-day").

Payloads

Merely loading malicious code onto a target does not constitute a full attack. Seldom is compromise the sole CW tactic; rather, post-compromise is where the CW tactic is implemented. Payloads consist of the post-compromise logic, and can be swapped out depending on the intended tactic. In this way, deployment and payload are separate tools but combined to form a single attack. Potential actions by malicious code are covered elsewhere in the book, here we mention a sample of possible payloads that have been seen in examples of CW.

A DoS attack is an overt example of CW, in that its effects will be plainly visible to the target; an important system will no longer be accessible or usable. DoS attacks were amongst the first malicious tactics to be labeled as actual CW maneuvers in state-on-state disputes. In 2007, Estonia suffered a massive DoS attack that lasted three weeks, and interrupted financial and governmental functions, while in a dispute with Russia.[60] Whether the attack was conducted by organs of the Russian state has never been established; however, CW does not necessitate actions are conducted only by nation states. Standards for attribution are not clearly defined, as we shall see.

The adoption of Supervisory Control and Data Acquisition (SCADA) network-connected systems for the U.S. infrastructure, such as power, water, and utilities,[61] has made DoS attacks a lethal weapon of choice. Offline SCADA systems could have spectacular kinetic results. In 2010, a covert attack given the name Stuxnet was targeted at nuclear facilities in Iran. It succeeded in causing widespread damage by replacing control code on SCADA systems, and aimed to remain covert by feeding the operators false instrument information while the attack was underway.

Control Consoles

In the commercial information security business, attack consoles are a known quantity. Software such as CORE IMPACT,[62] CANVAS[63] and Metasploit[64] provide interfaces that help the operator find vulnerabilities in target systems and launch exploits against those targets. The consoles ship with knowledge of hundreds of vulnerabilities, and include exploits for each one. The consoles also contain a multitude of payloads that can be attached to any exploit, that perform tasks such as account creation, command shell access or attacks against machines further in the network. An CW control console would contain the same elements as a commercial attack console, but also include the previously prepared vulnerability database as well as sport advanced telemetry to determine attack success.

Defensive Strategies

As far as prevention is concerned, experts agree that "there is no silver bullet against CW attacks."[65] In the US, defense against CW is split between two entities: the Department of Defense (DoD) is responsible for defending military resources, and the Department for Homeland Security (DHS) is responsible for protecting critical infrastructure. Purely in terms of military spending, the DoD requested $3.2 billion for cybersecurity in 2012, of which $159 million was intended for the U.S. Cyber Command (USCYBERCOM),[66] a military command who mission is to be the organization that "plans, coordinates, integrates, synchronizes, and conducts activities to: direct the operations and defense of specified Department of Defense information networks and; prepare to, and when directed, conduct full-spectrum military cyberspace operations in order to enable actions in all domains, ensure US/Allied freedom of action in cyberspace and deny the same to our adversaries."[67] From this mission statement, it is also clear that an offensive capability will be maintained. According to one military official, this was envisioned to be split approximately 85 percent defense and 15 percent offense.[68]

Without question, the defender's job is harder than the attackers in the environment that currently exists. This is not to say it is a truism; it is certainly possible to envision a world in which uniform security is applied throughout all connected networks, however that world does not exist today. The defender's dilemma from an CW perspective has multiple facets. Apart from the oft cited statement that a defender needs to cover all avenues of attack while the attackers needs only find a single vulnerability, CW also introduces the additional difficulty of defending networks that one potentially does not control. Would an CW defense command have full access to all critical infrastructure networks? This is unlikely; rather, individual actions would have to be delegated to administrators of those networks, who best know the ins and outs of their own networks.

For the most part, the attacks listed here are preventable and detectable. The problem facing a large target entity such as a sovereign nation is to coordinate its defense of many possible individual targets. Policies and procedures must be consistent and thoroughly followed. This is a mammoth task, given the heterogeneous nature of large computing systems. CW defense calls for rapid communication between all points worthy of defense and the central defense command.

Current solutions are of an organizational nature. Many developed countries have response teams such as the Computer Emergency Response Teams (CERT), but these deal only with technicalities of attacks. Higher-level involvement from government is required to act as a line of defense for CW. The U.S. DHS has forged a link with the private and public sector in the form of the US-CERT, with the blessing of a national strategy for cyber defense, and DHS coordinates with USCYBERCOM to ensure protection across military, government and critical infrastructure networks. In the U.K., a similar role is played by the National Infrastructure Security Co-ordination Centre.

South Africa, as an example country of the developing world, does not yet have a high-level commitment to digital defense; however, there are initiatives in the pipeline to address CW issues. A number of international efforts that aim at securing the Internet and preventing attacks such as the ones mentioned here have been implemented. One such initiative is the adoption of the European Convention of Cybercrime 2001, which deals with the commercial aspects of the Internet transactions. As far as the military aspects of CW are concerned, there have been calls from a number of countries, notably Russia, that the Internet be placed under control of the United Nations.[69]

One author suggests that, while completely excluding attackers is desirable, this may not be attainable, and so proposes that "the purpose of cyberdefense is to preserve [the ability to exert military power] in the face of attack,"[70] by concentrating on desirable qualities such robustness, system integrity and confidentiality. This is achieved by architecture decisions (air-gapped networks), policy positions (centralized planning including forensic abilities, decentralized execution), strategic analysis (determining the purpose of distributed attacks) and effective operations.

Key to any cyberdefense is attribution; without identifying the source of the attack one is unable to launch counterattacks. Attribution is rarely guaranteed except

when extremely simplistic markers are used. For example, using the source IP address of an attack does not imply that the owner of that addresses was aware of the attack. Botnets are typically built from thousands of vulnerable machines around the Internet and, while a machine may form part of an CW action, the owner cannot be punished militarily. Rather, the impact of the attack must be assessed in conjunction with information gleaned from other sources, in order to determine who the likely source was. Even then, the information may not be sufficient to point to state actors; industrial espionage or commercial attacks share many characteristics with CW, as we have already highlighted.

5. LEGAL ASPECTS OF CW

The fact that the Internet is, by definition, international implies that any criminal activity that occurs within its domain is almost always of an international nature.[71] The question that raises concern, however, is the degree of severity of the cyber attacks. This concern merits the following discussion.

Terrorism and Sovereignty

Today more than 110 different definitions of terrorism exist and are in use. There is consensus only on one part of the definition, and that is that the act of terrorism must "create a state of terror" in the minds of the people.[72]

The following definition of "workstation terrorism" as a variation of CW is quite suitable: "Computer terrorism is the act of destroying or of corrupting workstation systems with an aim of destabilizing a country or of applying pressure on a government,"[73] because the cyber attack's objective, *inter alia,* is to draw immediate attention by way of causing shock in the minds of a specific populace and thus diminishing that populace's faith in government.

Incidents such as hacking into energy plants, telecommunications facilities, and government Web sites cause a sense of instability in the minds of a nation's people, thereby applying pressure on the government of a particular country; therefore, these acts do qualify as terrorism and should be treated as such. Factual manifestations of war, that is, use of force and overpowering the enemy, ceased to be part of the classical definition of "war" after World War I,[74] and international writers began to pay more attention to the factual circumstances of each case to determine the status of an armed conflict. This is very significant for current purposes because it means that, depending on the scale and consequences of a cyber attack, the latter may be seen as a fully fledged war,[75] and the same restrictions—for example, prohibition of an attack on hospitals and churches—will apply.[76]

CW may seem to be a stranger to the concepts of public international law. This, however, is not the case, for there are many similarities between CW and the notions of terrorism and war as embodied in international criminal law.

The impact of the aforesaid discussion on sovereignty is enormous. Admittedly a cornerstone of the international law, the idea of sovereignty, was officially entrenched in 1945 in article 2(1) of the United Nations (UN) Charter.[77] This being so, any CW attack, whatever form or shape it may take, will no doubt undermine the affected state's political independence, because without order there is no governance.

Furthermore, the prohibition of use of force[78] places an obligation on a state to ensure that all disputes are solved at a negotiation table and not by way of crashing of the other state's Web sites or paralyzing its telecommunications facilities, thereby obtaining a favorable outcome of a dispute under duress. Finally, these rights of nonuse of force and sovereignty are of international character and therefore "international responsibility"[79] for all cyber attacks may undermine regional or even international security.

Liability Under International Law

There are two possible routes that one could pursue to bring CW wrongdoers to justice: using the concept of "state responsibility," whereby the establishment of a material link between the state and the individual executing the attack is imperative, or acting directly against the person, who might incur individual criminal responsibility.

State Responsibility

Originally, states were the only possible actors on the international plane and therefore a substantial amount of jurisprudence has developed concerning state responsibility. There are two important aspects of state responsibility

that are important for our purposes: presence of a right on the part of the state claiming to have suffered from the cyber attack and imputation of the acts of individuals to a state.

Usually one would doubt that such acts as cyber attacks, which are so closely connected to an individual, could be attributable to a state, for no state is liable for acts of individuals unless the latter acts on its behalf.[80] The situation, however, would depend on the concrete facts of each case, as even an *ex post facto* approval of students' conduct by the head of the government[81] may give rise to state responsibility. Thus, this norm of international law has not become obsolete in the technology age and can still serve states and their protection on the international level.

Attribution in the context of CW, without somebody coming forward to claim responsibility for the attack, may prove to be a difficult, if not impossible, task because to hold a state liable one would have to show that the government had effective control over the attacker but, though its conduct, failed to curtail the latter's actions directed at another state and threatens international peace and security.[82]

As a result, even though many attacks emanate from China, for example, the Chinese government will only be responsible if it supported or at least was aware of the attacker and went along with that attacker's plans. Solid forensic investigation would therefore be required before there can be any hope in attributing responsibility.[83]

Individual Liability

With the advent of a human rights culture after the Second World War, there is no doubt that individuals have become participants in international law.[84] There are, however, two qualifications to the statement: First, such participation was considered indirect in that nationals of a state are only involved in international law if they act on the particular state's behalf. Second, individuals were regarded only as beneficiaries of the protection offered by the international law, specifically through international human rights instruments.[85]

Individual criminal responsibility, however, has been a much more debated issue, for introduction of such a concept would make natural persons equal players in international law. This, however, has been done in cases of Nuremberg, the former Yugoslavia, and the Rwanda tribunals, and therefore,[86] cyber attacks committed during the time of war, such as attacks on NATO web sites in the Kosovo war, should not be difficult to accommodate.

What made it easier is the fact that in 2010, the Review Conference for the International Criminal Court introduced article *8bis* to the Rome Statute of the International Criminal Court ("ICC") which finally defined the crime of "aggression" as "the planning, preparation, initiation or execution, by a person in a position effectively to exercise control over or to direct the political or military action of a State, of an act of aggression which, by its character, gravity and scale, constitutes a manifest violation of the Charter of the United Nations".[87]

There is no doubt that use of unilateral force which threatens universal peace is prohibited in international law.[88] The difficulty in holding an individual responsible is two-fold: confirming jurisdiction of the ICC over the accused and proving the intention to commit the crime covered by the Rome Statute the ICC administers.

First, only persons who are found within the territory of the state that is a signatory to the Rome Statute or such state's nationals may be tried before the ICC. Secondly, there may be difficulties with justification of use of the same terms and application of similar concepts to acts of CW, where the latter occurs independently from a conventional war. Conventionally, CW as an act of war sounds wrong, and to consider it as such requires a conventional classification. The definition of "international crimes" serves as a useful tool that saves the situation: arguably being part of *jus cogens*,[89] crimes described by terms such as "aggression," "torture," and "against humanity" provide us with ample space to fit all the possible variations of CW without disturbing the very foundation of international law. Thus, once again there is support for the notions of individual criminal responsibility for cyber attacks in general public international law, which stand as an alternative to state responsibility.

In conclusion, it is important to note that international criminal law offers two options to an agreed state, and it is up to the latter to decide which way to go. The fact that there are no clear pronouncements on the subject by an

international forum does not give a blank amnesty to actors on an international plane to abuse the apparent *lacuna,* ignore the general principles, and employ unlawful measures in retaliation.

Remedies Under International Law

In every discussion, the most interesting part is the one that answers the question: What are we going to do about it? In our case there are two main solutions or steps that a state can take in terms of international criminal law in the face of CW: employ self-defense or seek justice by bringing the responsible individual before an international forum. Both solutions, however, are premised on the assumption that the identity of the perpetrator is established.[90]

Self-Defense

States may only engage in self-defense in cases of an armed attack[91] which in itself has become a hotly debated issue.[92] This is due to recognition of obligation of nonuse of force in terms of Art.2(4) of the UN Charter as being not only customary international law but also *jus cogens*.[93]

Armed attack, however, can be explained away by reference to the time when the UN Charter was written, therefore accepting that other attacks may require the exercise of the right to self-defense.[94] What cannot be discarded is the requirement that this inherent right may be exercised only if it aims at extinguishing the armed attack to avoid the conclusion of it constituting a unilateral use of force.[95] Finally, a state may invoke "collective self-defense" in the cases of CW. Though possible, this type of self-defense requires, first, an unequivocal statement by a third state that it has been a victim of the attack, and second, such a state must make a request for action on its behalf.[96]

Therefore, invoking self-defense in cases of CW today, though possible,[97] might not be a plausible option, because it requires solid proof of an attack, obtained promptly and before the conclusion of such an attack,[98] which at this stage of technological advancement is quite difficult. The requirement that the attack should not be completed by the time the victim state retaliates hinges on the fact that once damage is done and the attack is finished, states are encouraged to turn to international courts and through legal debate resolve their grievances without causing more loss of life and damage to infrastructure. Since most states would deny any support of or acquiescence to the actions of its citizens in executing an attack, the more realistic court that one would turn to in pursuit of justice is the ICC.

International Criminal Court

The International Criminal Court (ICC) established by the Rome Statute of 1998 is not explicitly vested with a jurisdiction to try an individual who committed an act of terrorism. Therefore, in a narrow sense, cyber terrorism would also fall outside the competence of the ICC.

In the wide sense, however, terrorism, including cyber terrorism, could be and is seen by some authors as torture.[99] That being so, since torture is a crime against humanity, the ICC will, in fact, have a jurisdiction over cyber attacks, too.[100]

Cyber terrorism could also be seen as crime against peace, should it take a form of fully fledged "war on the Internet," for an "aggressive war" has been proclaimed an international crime on a number of occasions.[101] Though not clearly pronounced on by the Nuremberg Trials,[102] the term "crime of aggression" is contained in the ICC Statute and therefore falls under its jurisdiction.[103]

103. Art.5(1)(d) of the Rome Statute of the International Criminal Court 1998, www.un.org/law/icc/statute/english/rome_statute(e).pdf (accessed on 13 October 2002).

Cyber crimes can also fall under crimes against nations, since in terms of customary international law states are obliged to punish individuals committing crimes against third states.[104] Furthermore, workstation-related attacks evolved into crimes that are universally recognized to be criminal and therefore against nations. P. Macalister-Smith, Encyclopaedia of Public International Law 876 (1992). Therefore, thanks to the absence of *travaux préparatoires* of the Rome Statute, the ICC will be able to interpret provisions of the statute to the advantage of the international community, allow prosecutions of cyber terrorists, and ensure international peace and security.

In practical terms the above will mean that a cyber attack will most probably be interpreted as part of "any weapon"[105] within the scope of the definition of "aggression" of the Rome Statute and the attacker will face the full might of the law as long as he/she is the national of the member state or finds him/herself within the physical territorial boundaries of the state that is party to the Rome Statute even though the attacker's conduct may not be enough to make the country of its nationality liable for what he/she did.[106]

Other Remedies

Probably the most effective method of dealing with CW is by way of treaties. At the time of this writing, there has been only one such convention on a truly international level, the European Convention on Cybercrime 2001.

The effectiveness of the Convention can be easily seen from the list of states that have joined and ratified it. By involving such technologically advanced countries as the United States, Japan, the United Kingdom, Canada, and Germany, the Convention can be said to have gained the status of instant customary international law,[107] as it adds *opinio juris* links to already existing practice of the states.

Furthermore, the Convention also urges the member states to adopt uniform national legislation to deal with the ever-growing problem of this century[108] as well as provide a platform for solution of disputes on the international level.[109] Finally, taking the very nature of CW into consideration, "hard" international law may be the solution to possible large-scale threats in future.

The fact that remedies bring legitimacy of a rule cannot be overemphasized, for it is the remedies available to parties at the time of a conflict that play a decisive role in the escalation of the conflict to possible loss of life. By discussing the most pertinent remedies under international criminal law, the authors have shown that its old principles are still workable solutions, even for such a new development as the Internet.

Developing Countries Response

The attractiveness of looking into developing countries' response to an CW attack lies in the fact that usually these are the countries that appeal to transnational criminals due to lack of any criminal sanctions for crimes they want to commit. For purposes of this chapter, the South African legal system will be used to answer the question of how a developing country would respond to such an instance of CW.

In a 1989 "end conscription" case, South African courts defined war as a "hostile contest between nations, states or different groups within a state, carried out by force of arms against the foreign power or against an armed and organised group within the state."[110] In the 1996 *Azapo* case, the Constitutional Court, the highest court of the land, held that it had to consider international law when dealing with matters like these.[111] In the 2005 *Basson* case, the Constitutional Court further held that South African courts have jurisdiction to hear cases involving international crimes, such as war crimes and crimes against humanity.[112]

A number of legislative provisions in South Africa prohibit South African citizens from engaging, directly or indirectly, in CW activities. These Acts include the Internal Security Intimidation Act 13 of 1991 and the Regulation of Foreign Military Assistance Act 15 of 1998. The main question here is whether the South African courts would have jurisdiction to hear matters in connection therewith. A number of factors will play a role. First, if the incident takes place within the air, water, or *terra firma* space of South Africa, the court would have jurisdiction over the matter.[113]

The implementation of the Rome Statute Act will further assist the South African courts to deal with the matter because it confers jurisdiction over the citizens who

commit international crimes. It is well known that interference with the navigation of a civil aircraft, for example, is contrary to international law and is clearly prohibited in terms of the Montreal Convention.[114]

A further reason for jurisdiction is found in the 2004 Witwatersrand Local Division High Court decision of *Tsichlas v. Touch Line Media*,[115] where Acting Judge Kuny held that publication on a Web site takes place where it is accessed. In our case, should the sites in question be accessed in South Africa, the South African courts would have jurisdiction to hear the matter, provided that the courts can effectively enforce its judgment against the members of the group.

Finally, in terms of the new Electronic Communications and Transactions (ECT) Act,[116] any act or preparation taken toward the offense taking place in South Africa would confer jurisdiction over such a crime, including interference with the Internet. This means that South African courts can be approached if preparation for the crime takes place in South Africa. Needless to say, imprisonment of up to five years would be a competent sentence for each and every participant of CW, including coconspirators.[117]

6. HOLISTIC VIEW OF CYBER WARFARE

This chapter has addressed the four axes of the CW model[118] presented at the beginning of this discussion: technical, legal, offensive, and defensive. Furthermore, the specific subgroups of the axes have also been discussed. For the complete picture of CW as relevant to the discussion at hand, however, Figure 58.2 places each subgroup into its own field.[119]

7. SUMMARY

This discussion clearly demonstrated that CW is not only possible, it has already taken place and is growing internationally as a preferred way of warfare. It is clearly demonstrated that successful strategies, offensive or defensive, are dependent on taking a holistic view of the matter. Information security professionals should refrain from focusing only on the technical aspects of this area, since it is shown that legal frameworks, national as well as international, also have to be considered. The prevailing challenge for countries around the globe is to foster collaboration among lawyers, information security professionals, and technical IT professionals. They should continue striving to at least keep the registry of CW arsenal and remedies updated, which may, in turn, incite adversaries to provide us with more material for research.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The technical side of CW deals with technical exploits on one side and offensive measures on the other.
2. True or False? It is clear that CW is all about information superiority because "the fundamental weapon and target of CW is information.".
3. True or False? In addition to training personnel and producing cyber weapons, the preparation stage also consists of a wide range of information gathering activities.
4. True or False? CW does not require the infrastructure investment that physical arms do,[120] however it requires highly trained personnel to develop cyber weapons and the process of training to the required skill levels occupies a significant portion of activities prior to hostilities breaking out.
5. True or False? The reconnaissance phase of preparation focuses on identifying government organs, industries, infrastructure, companies, organizations and individuals that are not potential targets.

114. Montreal Convention of 1971.
115. *Tsichlas v. Touch Media* 2004 (2) SA 211 (W).
116. Electronic Communications and Transactions Act 25 of 2002.
117. Electronic Communication and Transaction Act 25 of 2002.
118. Supreme Court Act 59 of 1959 (South Africa).
119. Implementation of the Rome Statute of the International Criminal Court Act 27 of 2002 (South Africa).
120. Of the $707.5 billion requested for the U.S. Department of Defense 2012 budget, $159 million was earmarked for the Cyber Command.

Multiple Choice

1. What type of scanning is a common activity in the commercial security industry, where numerous scanners exist?
   - **A.** Qualitative analysis
   - **B.** Vulnerabilities
   - **C.** Data storage
   - **D.** Vulnerability
   - **E.** DHS
2. What is an important decision in deciding on a CW strategy?
   - **A.** Network attached storage (NAS)
   - **B.** Risk assessment
   - **C.** Scale
   - **D.** Subcomponents
   - **E.** Bait
3. What type of weapons include social engineering techniques and psychological operations *(psyops)?*
   - **A.** Organizations
   - **B.** Fabric
   - **C.** Psychological
   - **D.** Risk communication
   - **E.** Security
4. There are ______________ differences between weapons that exist in the physical realm and those that exist within the cyber realm, and the differences are useful to highlight.
   - **A.** Cabinet-level state office
   - **B.** Non-subtle
   - **C.** Infrastructure failure
   - **D.** SAN protocol
   - **E.** Taps
5. What type of database is the result of an effort to collect information about all known security flaws in software?
   - **A.** Irrelevant
   - **B.** Consumer privacy protection
   - **C.** IP storage access
   - **D.** Vulnerability
   - **E.** Unusable

System Security

Lauren Collins
kCura Corporation

1. FOUNDATIONS OF SECURITY

Since the inception of technology, data security has revolved around cryptography. Since cryptography is only as good as the ability of a person or a program, new methods are constantly being implemented as technology becomes more sophisticated.

Differentiating Security Threats

Cipher text and secret keys are transported over the network and can be harvested for analysis, as well as impersonate a source or, worst case, cause a service denial. Thus, aiding encryption and complex distribution methods, a network needs to be secure and elegant. That is, the network should have applicable appliances that monitor and detect attacks, intelligence that discriminates between degradations/failures and attacks, and also a convention for vigorous countermeasure strategies to outmaneuver the attacker. Consequently, network security is a completely separate topic from data security.

Incident levels should be defined as low, medium, high, and catastrophic. Level 1 helpdesk professionals should be equipped to handle tasks such as these. Low-severity breach examples are:

- Malware or virus-infected system that is on the local area network (LAN)
- Account credentials compromised with general rights
- Spam e-mail incidents

Medium-severity incidents should be escalated to a system administrator or engineer. These would include:

- Website destruction
- Spam impacting an entire environment's performance
- Sensitive information leak
- Account credentials compromised with administrative rights

High-severity incidents would be handled by a senior engineer, architect, manager, or director. Examples include:

- Hacking of the environment
- International, federal, or state law violations:
  1. HIPAA (Health Insurance Portability and Accountability Act)—medical field
  2. FERPA (Family Education Rights and Privacy Act)—education field
  3. Pornography
  4. Illegal download and sharing of copyright material (music, movies, software)
- Disruption of business due to malicious acts
- Breach to systems where an act is in progress of leaking confidential information and hosts need to be disconnected altogether to halt the process

Modern enterprises and their security teams need to be prepared to work with an onslaught of new, rapidly evolving menaces. From novice script writers to sophisticated hackers working for criminal organizations, if an enterprise does not have policies in place to handle threats, they will pay the price in disconcerting, expensive data breaches. An effective threat management platform is one vibrant component for any security team who deals with evolving threats from the world outside of their control. Resources must be allocated to implement such a platform, and an agenda should be put in place while also testing the program. The following are five best practices to increase effectiveness when implementing a vulnerability management program:

1. **Control notifications and alerts.** The most important thing a company can do is get a handle on threat management and ensure an IT professional is available to review and respond to a notification or alert. In order to accomplish this, one or more individuals need to have responsibility assigned to them so that everyone is aware of which point person(s) will review logs and audits on a daily basis, or in the event of an attack. It is not uncommon to see organizations assign different

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00059-3

individuals to review different alerts consoles. Case in point: A firewall expert may review firewall changes and logs, while an applications engineer may review the logs and alerts from the Web application firewalls.

2. **Consider a holistic view.** In the domain of discovery avoidance, attackers are growing more and more cutting edge. A multichannel attack is the superficially innocuous spear where a user clicks on a link that leads to a rogue site that has been designed to look authentic. This user may then be deceived into entering sensitive data or clicking another link affecting the target machine with a bot. Once that user's sensitive information has been collected, the attacker can now attempt to log in to a system and dive deeper into the network for more valuable information. To catch multichannel attackers, alerts need to be organized in a meaningful way from all the systems into a single console where correlation rules filter activities and, when combined, creates a single, organized attack.
3. **Slash false positives.** Have you received so many email alerts that you ignore certain alerts and immediately delete them without further investigation? This author surely has. Excessive alerts and false positives intensify the noise ratio so greatly that it can be challenging (if not impossible) to scrutinize data to find truly malicious occurrences. If an organization's administrators cannot differentiate important alert signals through all the less significant events, the system becomes useless. To reduce the number of false positives fabricated, an enterprise should first analyze the alert output of its threat-warning console and then determine if the rules can be fine-tuned to reduce the false-positive noise. Also, filtering the alerts by level of confidence may be useful so that administrators can see which alerts are more likely to be relevant. One way to lower the alert levels without losing the critical alerts would be to set the threshold levels that match normal activity on the network. For example, if a company forces all users to change the password on the same 30-day cycle, they might find that failed logins increase significantly on the day after the end of the cycle. To account for this occurrence, a rule that normally signals an alert after two failed logins could be increased to four failed logins, only on days following the password change. Those logins could also be linked to other threat indicators, such as attempts to log in using the same username from multiple IP addresses, to increase accuracy.
4. **Integrate thresholds and procedures.** As mentioned in #3, aggregating threat information into a single console gives firms threat visibility across the entire infrastructure. You want more visibility? A firm can integrate that single console view with their new, refined thresholds and procedures. That's right: Always keep the mind-set that you want to be a moving target. By treating your monitoring system the same way as your infrastructure, as the infrastructure grows please ensure that your monitoring system accommodates that growth. Rules and log aggregation tools rightfully parse through information and flag legitimate attack activity for further investigation or response. Another key to integrating effectively is to make sure engineers and admins have access to proper escalation paths, communication protocols, and approved response activities.
5. **Corroborate remediation events.** In a heated situation, one can easily overlook validating events in logs upon review. Even when performing routine maintenance such as patch management, many firms fail to close the remediation loop by validating the entries. Did the patch get loaded properly? Did it close the intended vulnerability? Without testing, an organization cannot be certain the remediation was successful and the threat exposure gap was closed. There is a threat management cycle, and it must be completed utilizing steps for validation. This may include rescanning systems to validate patches and also, by performing application and network penetration, testing to confirm that fixes or controls are blocking vulnerabilities as expected.

Hardware and Peripheral Security

Network security deals with the secure transport of data. It requires more awareness and a thorough understanding of the different types of mechanisms and attack scenarios and how they can be differentiated. A topic these days for a controversial discussion is whether to allow employees to bring your own device (BYOD) to the office. Whether it is a mobile device, a desktop or laptop, or a tablet, companies must have policies in place to address security and who owns the data on the device. Several places institute a policy where an application like ActiveSync is used, and upon an employee's termination the device(s) can be wiped of all data. That usually sounds good to the employee upon signing the consent form, but imagine losing all your contacts, music and apps, and all the data on the device. Given the breadth of end users on mobile devices and the diversity of use cases, BYOD is driving not just the need for performance upgrades but also much more fine-grained network access controls.

There is also a method for detecting signatures and how that is used to classify attacks and enhance network security. Computing platforms used in the field are intricate and require interaction between multiple hardware components (processor, chipset, memory) for their normal operation. Maintaining the security of the platforms translates to verifying that no known security exploits are present in the runtime interaction between these hardware units which can be exploited by attackers. However, given the large number of state elements in the hardware

units and many control signals influencing their mutual interaction, validating the security of a commercial computing platform thoroughly can be complicated and intractable. By exemplifying challenges to correctly implement security, it is necessary to provide examples of various classes of hardware-oriented security attacks. The following are logic and tools to use:

- For the enthusiastic newbies, there are pre-made, entry-level tool packages as shown in Figure 59.1. You can diagnose your hardware without writing even one line of code. Automatically generate your device driver, and run this nifty tool on any operating system.
- Digital oscilloscopes, logic analyzers, device programmers, and spectrum analyzers are all available on eBay and are no longer out of reach for hardware hackers. Utilizing this equipment, one can take advantage of essentially the same equipment used in production engineering facilities. In Figure 59.2, a logic analyzer displays signals and program variables as they change over time.
- Free tools are available that are open-source Printed Circuit Board (PCB) design tools, which include electronic design automation (EDA). These tools allow hackers to dive deep into the game without bringing a ton of years of electrical engineering to the table. Schematic captures are done interactively with an editor tool and allow one to gain insight on arrays and other miniscule passive components.

The magnificence of hardware hacking, similar to engineering design, is that rarely is there only one correct process or solution. The author's personal hardware hacking methodology consists of the following subsystems:

1. *Gather information:* Hardware hacking, much like any technology, is about gathering pertinent information from an assortment of resources. The answers include product specifications, design documents, marketing data, forums or blogs, and of course, social network sites. Social engineering techniques can be used to manipulate a human victim into divulging applicable information. Many will simply call a vendor's sales or technical engineer directly and invoke interest in a product, and will ask open-ended questions to obtain as much information as the respondent is willing to divulge.
2. *Hardware stripping*: This consists of obtaining the hardware and disassembling it to gather evidence regarding system functionality, design practices, and potential attack areas to target. The primary goal of tearing hardware down is to gain access to the circuit board, which will then allow a hacker to identify high-level subsystems, component types, and values, and in some cases, locate any antitampering mechanisms that would specifically impede physical attack or tampering. Clearly, having direct access to the circuitry allows an attacker to modify, remove, or add components.
3. *Assess external accessibility*: Any product interface that is made accessible to the outside world is an avenue of attack. Programming, debugging, or admin interfaces are of extreme interest, as it allows a hacker direct access to control the device with the same authority as a tech or engineer.
4. *Reverse engineering*: By extracting program code or data and disassembling the contents, a hacker will be able to obtain full insight into the product operation and functionality and potentially modify, recompile, and insert the code back into the product in order to bypass security mechanisms or inject malicious behavior.

The prolific adoption of embedded systems has led to a blurring between hardware and software. Software

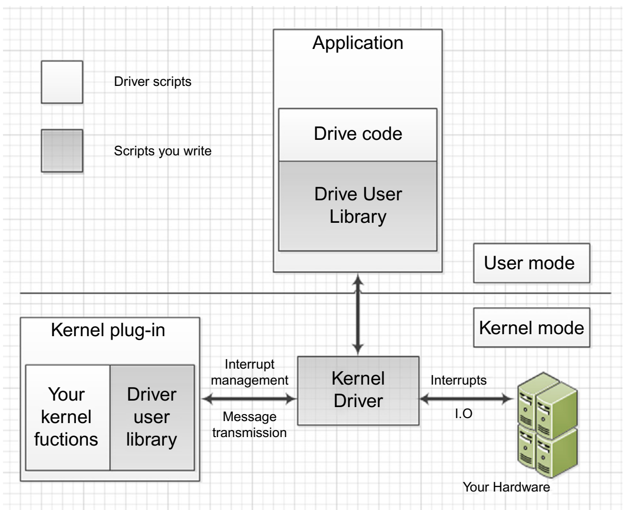

FIGURE 59.1 Architecture to access your hardware directly from the application level.

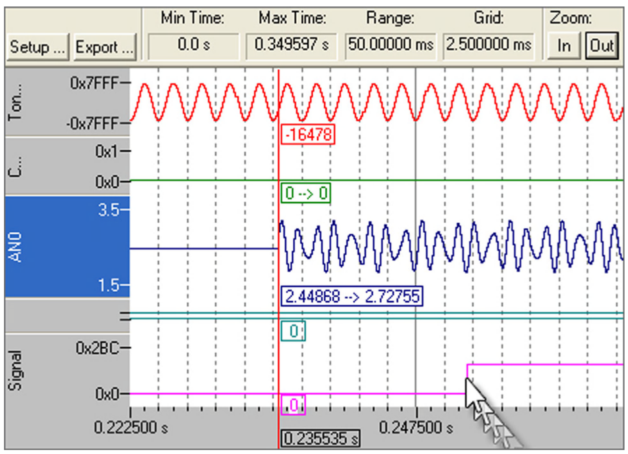

FIGURE 59.2 Signals recorded by the logic analyzer are easily configured to accurately measure signal changes and delta information, and will even allow you to zoom into the area at any point where a signal changed.

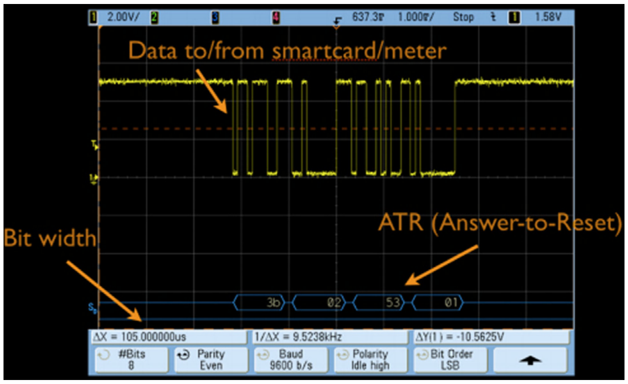

FIGURE 59.3 Oscillator output displaying the transmission between the smartcard and meter.

hackers can now use their skills, tools, and techniques in an embedded environment against firmware without having to grasp hardware-specific paradigms.

The best way to close the gap between hardware and software hacking is to allow them to work together in order to achieve the desired results. The leading example will enlighten the reader as to why electronic devices used in security or financial applications cannot and should not be fully trusted without thorough analysis and stress testing.

Example

Many large cities have installed digital parking meters throughout the streets, and claim they are secure and tamper proof. While a hacker has many opportunities to attack a metering device, this example focuses on the easily accessible, external smartcard interface. By placing an uninhabited shim between the smartcard and meter, the shim was used to gain the requisite signals and the communication was then captured using an oscilloscope. (It's good to have friends with cool toys). The serial decoding function of the oscilloscope, displayed in Figure 59.3, points out the actual data bytes that were transmitted from the meter, then to the card, and finally received by the meter from the card.

Patch Management and Policies

Does anyone receive auto-generated email alerts that are excessive, false positives? Not only can it be impossible to examine all of the information, but to assert whether or not the information is truly malicious is another tedious task. Many times this author has ignored countless emails when too many false positives have occurred, which could have been a warning of potential issues. Anytime an environment changes, individuals should be attentive to editing the notifications of the environment. An example would be when maintenance will be performed where five servers will be restarted multiple times for patches. The alert should be paused for these five servers in an effort to not trigger false alerts where the rest of the team is not aware of the maintenance. If the team is aware of the maintenance, this is a prime example of a false alert that is overlooked, and think through this example happening 10 times a day. Hardly anyone will pay attention to the alerts if 99.99 percent of them are false positives.

Implementing consistent, updated patches may be cost prohibitive for a company, especially for a mission-critical environment. It is necessary to maintain the integrity of an environment and the data by applying both operating system and application security patches and updates. The security team or IT manager needs to ascertain a criterion for procedures as well as an established time frame to apply patches. Windows patches may alter program functionality and capability so severely that users are unable to effectively perform their job function. For instance, some Web applications were not compatible with Internet Explorer version 9, and if updates are set to automatic, troubleshooting this issue could be quite time consuming. Unless patches have been tested in a testing environment, and were successful, there should not be any patches released to the user community. There are patch management packages that offer automation, of course, after testing has proved to be successful. Figure 59.4 depicts an example of a patch management program. Patch names are shown in the left-hand column, the next column classifies the patch, then displays whether or not the patch was installed, and shows the release date along with the arrival date.

Package management systems are charged with the task of organizing all of the packages installed on a particular system. The characteristics of architectural tasks are shown in the following checklist: An Agenda for Action for Implementing Package Architectural Tasks.

IT admins may install and maintain software-utilizing instruments other than package management software. Dependencies will need to be managed, and additional

An Agenda for Action for Implementing Package Architectural Tasks

Please see the following package architectural characteristics tasks (check all tasks completed):

_____**1.** Manage dependencies to ensure a package is installed with all packages required.
_____**2.** Group packages related to utility.
_____**3.** Upgrade software to latest (tested) versions from a file repository.
_____**4.** Apply file records to manage encapsulated files.
_____**5.** Verify digital signatures upon substantiation of the source packages.
_____**6.** Corroborate file checksums to confirm authentic, comprehensive packages.

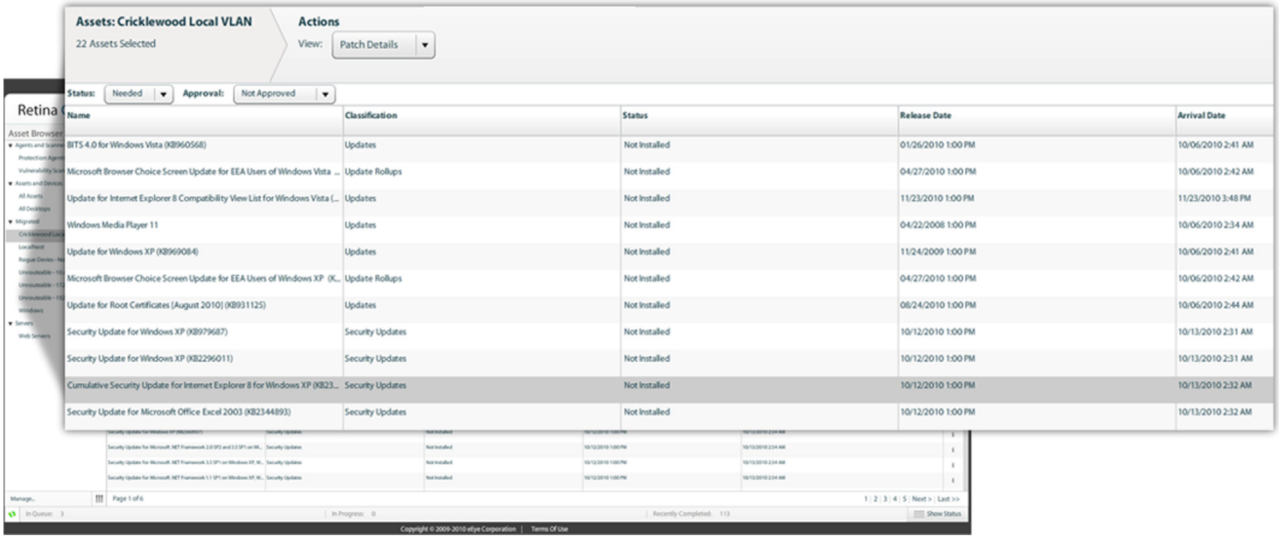

FIGURE 59.4 Patch management software is a helpful tool to track patches and whether or not the patch has been applied to a client.

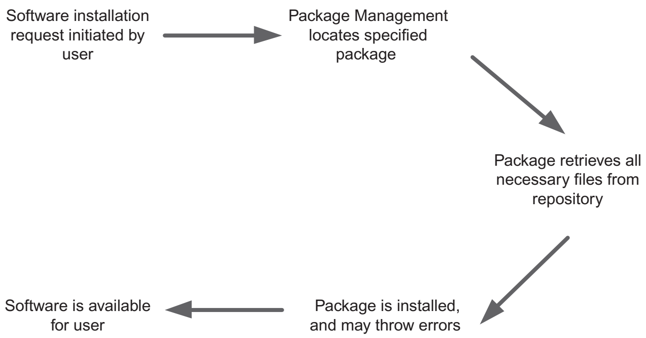

FIGURE 59.5 Cycle of a patch management software installation.

changes may have to be assimilated into the package manager. This does not seem like a very efficient way to some, although having control of source code and the ability to manipulate code may be an attractive advantage. In addition to the manual process of installing patches, license codes may need to be manually activated. When dealing with large environments, can you fathom typing in an activation code thousands of times? Not only is this counterproductive, but it is severely inefficient as noted in Figure 59.5.

Each hardware and software vendor may have differing frequencies for their approach to patch releases. Microsoft has "Patch Tuesday" which occurs the second Tuesday of a month. When Windows updates are set to Automatic, a computer will apply patches as they're released. These patches may not be tested in an environment, hence the importance of setting updates to manual and having a patch management system. A good practice is to release patches once a month, and to release them roughly a week after the vendor has published the patch. Network hardware patches may not need to be applied, depending on the environment and whether or not the patch will compromise the function of the equipment. Additionally, patches may alter the command set or configuration, so be sure to back up your configuration prior to applying any patch or firmware update.

2. BASIC COUNTERMEASURES

With only 30 to 40 percent of firewall rules in use, security vulnerabilities arise due to misconfigurations. An organization may expose its network to access for which there is no business purpose.

Security Controls and Firewalls

At times, it is not an issue of data sneaking past network controls, but misconfiguration and reluctance to fix issues fearing that the business may be interrupted as changes are implemented. When a team identifies all users' network access, they are able to shape and control access based off rights and proper use. Risk is reduced by blocking unnecessary access paths prior to a security incident occurring. When a consultant is brought into a firm and shows the IT director all the paths, there are holes in the network that could be used for unauthorized access; heads roll, and a plan is soon in place to rectify the holes. Other firms are relatively weak when it comes to monitoring the data right in front of them. While many firms have the appropriate technologies, policies and awareness programs need to be in place for users and their resources. The level of awareness also needs to be known in unmanaged IP devices due to the number of vulnerabilities only increasing over time.

There are many options out there when considering a firewall for your environment. A great deal of firewalls also

include other security features: unified threat management (UTM), data loss prevention (DLP), content filtering, intrusion detection and prevention services (IPS), and vulnerability management. A firewall is such a critical component of your infrastructure, and fault tolerance should not be considered optional. A network should be designed so that it is resilient enough to handle the failure of a single firewall. Most concerns with UTM are the amount of processors eaten up by the jobs being performed. With large organizations, you may find you're better off with specialty devices fulfilling each of the security functions covered by UTM. Conversely, UTMs are a great benefit for smaller companies with lower network traffic, especially where costs are concerned when selecting a bundled option.

There is a huge amount of virtual networks out there, both at company office sites and at data center facilities. Virtual firewalls are a way to maximize your security budget by consolidating multiple logical firewalls onto a single platform. Each virtual firewall has its own rules, interfaces, and configuration options that are completely independent from other virtual firewalls running in other infrastructure platforms, but in the same environment. Having this feature also adds the element that a configuration mistake will not only affect performance, but may block all traffic getting to and from the affected segment.

Whether the firewall is hardware or software based, the objective is to control whether or not traffic should be allowed in or out based on a predetermined set of rules. Imagine a security analyst parsing through hundreds pages of logs, where this would only account for 10 to 30 minutes of traffic and determining whether or not rule sets need to be altered.

Case in point: Also envision an issue arising where a complaint comes in from your company's Internet provider stating that your IP address raised a red flag and downloads of copyrighted material were performed. This Internet provider can even state the name of the movie that was downloaded. Other than the Internet provider expecting a response back describing the steps that will be taken to prevent subscriptions from downloading illegal content, internal management at this company expects actions to be taken as well. This is when a security admin will go in and parse through logs searching for the type of file that was downloaded, and if this was not already blocked it will need to be. Bit torrents may need to be blocked. However, depending on the type of work a company performs, there are many legal and necessary uses of bit torrents.

Application Security

An increasing number of organizations are questioning whether they should put a Web application firewall in front of an application, or if the code should just be fixed. Entire teams have committed to securing an application. Consultants travel all over to perform a deep dive of an application environment and suggest measures to correct loopholes. If the strategy shifted toward incorporating applications coupled with Web application firewalls, the company would be more productive integrating this plan as part of its broader application security architectures. Whether Structured Query Language (SQL) attacks or cross-site scripting was the vulnerability, a financial institution would still need about two years to patch 99 percent of the flaws in its applications. By this time, several revisions of the application will have been released, sending teams in downward spirals chasing their tails.

If you ask your customers or colleagues, there is not much collaboration between the security and development teams in an organization. The worst part is that developers are not usually motivated to address secure application development unless they are forced to in the midst of a security incident or to prove compliance initiatives. Developers are sometimes reviewed based on how much software they can build and release on time, and no one holds them accountable for the security portion. The application security challenge has become so difficult to address through development that an alternative plan relies on integrating defensive technologies like Web app firewalls, database audit and protection (DAP), and XML gateways into the infrastructure. Using Web app firewalls in conjunction with coding frameworks fits nicely into filling security functions.

Is it faster, cheaper, and more effective to use a device to shield an application from a security flaw? It may be, but meanwhile hacking strategies are also becoming more accessible, faster, free, and more attractive. Web application firewalls are an appliance, or server, that can monitor and block traffic both to and from the applications. They are common in companies such as credit-card payment firms, which have frequent code reviews. You cannot throw a piece of hardware in front of all applications and expect it to solve all your problems because it is a good idea to build your applications securely from the start.

Hardening and Minimization

The practice of safeguarding systems is to reduce the plane of exposure, also referred to as hardening. An environment where a multitude of cross-functional work is performed can increase the scale of the vulnerability surface since that plane grows larger based on the scope of work. A security engineer can reduce available trajectories of incidents by removing unnecessary software that is not related to business use, deleting usernames or logins for employees or contractors who are no longer at the firm, and also by disabling or removing unnecessary services.

Linux has so many powerful tools where a patch can be applied to the kernel and will close open network

ports, integrate intrusion detection, and also assimilate intrusion prevention. While this may work for a smaller firm, the author does not recommend this solution for a robust, large environment. Exec Shield is an undertaking Red Hat began in 2002, with the goal of condensing the probability of worms or other automated remote breaches on Linux systems. After this was released, a patch was necessary that emulated a never execute (NX) bit for a CPU that lacks a native NX implementation in the hardware. This NX bit is a tool used in CPUs to isolate sections of memory that are used by either the storage of processor instructions, or code, or for storage of data. Intel and AMD now also use this architecture; however, Intel identifies this as execute disable (XD), and AMD appointed the name enhanced virus protection. An operating system with the capability to emulate and take advantage of a NX bit may prevent the heap memory and stack from being executable, and may also counteract executable memory from being writable. This facilitates the prevention of particular buffer overflow exploits from prospering, predominantly those that inject and execute code, for example, Sasser and Blaster worms. Such attacks are dependent on some portion of the memory, typically the stack, to be both executable and writable, and if it is not the stack fails.

In the realm of Wi-Fi, companies must implement tight network security controls. Device authentication is another layer of security that would not allow proximity hacking. For example, a car next door is parked in a parking lot and can easily hack onto a firm's network. Guest wireless is a common component to segregate guests off the company's network. With that being said, corporate users might be tempted to switch over to the public, guest network where there are fewer or no controls. This is where leakage may occur. Best practice would be to set up a guest network that issues only temporary credentials to allow connections. This will deter any employees from accessing and utilizing an unsecure connection, and also will not allow former guests or employees' access.

In an ideal world, all traffic would be monitored, but when a company does a cost/benefit analysis, it may seem excessive to do so. Directors make a judgment call based on the threat analysis to ascertain whether it is worth putting these controls into certain segments of the network. It is a terrible practice to have everyone on the same network, but unfortunately that is what most companies do. Whether money is not abundant enough to segment a network, or a security team is not in place to implement policies and maintain them, this is prevalent in most small and medium-sized businesses.

The best approach would be to have anomaly detection that baselines the network traffic and assesses patterns, identifying the anomalies. For the determined attacker, you need to be prepared on the host; so, you need to have it tightly secured where users do not have admin rights. Having a good anti-virus and anti-malware software platform in place is mandatory, too. Depending on the business purpose, classifying data and ultimately segregating that data is also key. The only way to access that data would be through a secured connection through Citrix or some other key/fingerprint mechanism.

In programming, minimization is the method of eradicating all unnecessary character from source code, keeping its functionality. Unnecessary characters may include comments, white space characters, new line characters, comments, and occasionally block delimiters, which are used to enhance comprehension to the code but are not required for that code to execute. In computing machine learning, a generalized model must be selected from a finite data set, with the consequent challenge of overlifting. The model may become too strongly modified to the particularities of the training set and oversimplifying new data. By balancing complexity to institute security against success to seamlessly provide data to groups across the entire firm, one can master risk minimization.

3. SUMMARY

This chapter focused on how the objective of systems security is to improve protection of information system resources. All organizational systems have some level of sensitivity and require protection as part of good management practice. The protection of a system must be documented in a systems security plan.

The purpose of the systems security plan is to provide an overview of the security requirements of the system and describe the controls in place or planned for meeting those requirements. The systems security plan also delineates the responsibilities and expected behavior of all individuals who access the system. The systems security plan should be viewed as documentation of the structured process of planning adequate, cost-effective security protection for a system. It should reflect input from various managers with responsibilities concerning the system, including information owners and the system owner. Additional information may be included in the basic plan, and the structure and format should be organized according to organizational needs.

In order for the plans to adequately reflect the protection of the resources, a senior management official must authorize a system to operate. The authorization of a system to process information, granted by a management official, provides an important quality control. By authorizing processing in a system, the manager accepts its associated risk.

Management authorization should be based on an assessment of management, operational, and technical controls. Since the systems security plan establishes and documents the security controls, it should form the basis

for the authorization, supplemented by the assessment report and the plan of actions and milestones. In addition, a periodic review of controls should also contribute to future authorizations. Re-authorization should occur whenever there is a significant change in processing, but at least every three years.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Since the inception of technology, data security revolves around cryptography.
2. True or False? Cipher text and secret keys are transported over the network and can be harvested for analysis, and furthermore to impersonate a source or, worst case, cause a service denial.
3. True or False? Network security deals with the insecure transport of data.
4. True or False? Implementing inconsistent, updated patches may be cost prohibitive for a company, especially for a mission-critical environment.
5. True or False? With only 30 to 40% of firewall rules in use, security vulnerabilities arise due to misconfigurations.

Multiple Choice

1. At times, it is not an issue of data sneaking past network controls, but __________ and reluctance to fix issues fearing that the business may be interrupted as changes are implemented.
   A. qualitative analysis
   B. vulnerabilities
   C. data storage
   D. misconfiguration
   E. DHS
2. There are many options out there when considering a ____________for your environment.
   A. firewall
   B. risk assessment
   C. scale
   D. subcomponents
   E. bait
3. There are an increasing number of organizations questioning whether they should put a(n) ______________ in front of an application, or if the code should just be fixed.
   A. organizations
   B. fabric
   C. psychological
   D. Web application firewall
   E. security
4. The practice of safeguarding systems is to reduce the plane of exposure, also referred to as:
   A. cabinet-level state office
   B. nonsubtle
   C. hardening
   D. SAN protocol
   E. taps
5. The purpose of the ______________ is to provide an overview of the security requirements of the system and describe the controls in place or planned for meeting those requirements?
   A. systems security plan
   B. consumer privacy protection
   C. IP storage access
   D. vulnerability
   E. unusable

Securing the Infrastructure

Lauren Collins
kCura Corporation

1. COMMUNICATION SECURITY GOALS

Since the inception of technology, data security revolves around cryptography. Because cryptography is only as good as the ability of a person or a program, new methods are constantly implemented as technology becomes more sophisticated.

Network Design and Components

Cipher text and secret keys are transported over the network and can be harvested for analysis; furthermore they can impersonate a source or, worst case, cause a service denial. Thus, to aid encryption and complex distribution methods, a network needs to be secure and elegant. That is, the network should have applicable appliances that monitor and detect attacks, intelligence that discriminates between degradations/failures and attacks, and also a convention for vigorous countermeasure strategies to outmaneuver the attacker. Consequently, network security is a completely separate topic from data security; however, the devices chosen must complement your infrastructure.

The accumulation of advances in key technologies has enabled companies to envision the implementation of an infrastructure with no limitations. Among these advances are those in materials that underlie electronic components and optical technologies, including optical fibers. Improvements in electronic integrated circuits include both the speed at which these circuits can perform their functions and the achievable complexity that allows a single chip to perform complex tasks. Advances in signal processing techniques that use electronic circuits and software to convert information and information-carrying signals into forms suitable for transport over short or long distances arrange for data to be stored, processed, and transmitted lightning fast. Such advantages have even allowed engineers and scientists to work harder and think further out to develop new technologies to follow suit on hardware and software transformations. Significant progress is required to realize and appreciate the vision of affordable media.

New algorithms and approaches complement the speed of transport networks, coupled with complex connection and session establishment and management. Total network approaches are required to resolve effective management of a cutting-edge infrastructure solution. Large costs are associated with installation and building out of fiber networks needed to provide an objective, robust network. Networks must be scalable and support multiple types of media, including coax, fiber, copper, and wireless, using both the shared media and switched approaches. Premise access must support the multiplexing of video, voice, and data sources requiring varied quality-of-service (QoS) levels and various bandwidths.

Several backbone options and avenues are available, due mostly to the era of electronic trading. These can be comprehensively separated into time division techniques and wavelength division techniques. Determining the potential of each technology would significantly contribute to a company's success, depending completely on the type of business involved. The time domain limits are determined by the speed of the electro-optic transducers, of the required buffer and memory, and of the switching and control logic required to manage the system. Additionally, high-speed regeneration technologies play a pivotal role in delivering benefits of time-division techniques to the system. Take long distances into consideration: Fiber properties such as loss and dispersion in the fiber limit the capabilities of the fiber span. Optical amplification, attenuators, and dispersion compensator devices can restore impairments induced by the fiber properties and allow the media to match the heat and light of the equipment chosen. Wavelength converters, wavelength filters, and wavelength division multipliers enable use of a greater capacity of the fiber. Optical regeneration techniques permit clock recovery and lead to full regeneration capabilities in the optical domain, avoiding unnecessary optical to electrical conversions.

Switching and Routing

Backbone networks require switches with tremendous capacity. Switches of this scale are not commercially available today, and much research, configuration, and testing must be done to make them perform a specific job. Total system throughputs of 15 terabits per second are possible with the latest and greatest equipment out there, and more is to come. A challenge for switching systems is to achieve systems that the access network can scale to either the amount of users or the amount of traffic being pumped through the network. Signaling systems for switch control must support a richer communication model than prior generations of switches. User channels can operate at any rate from a couple bits per second to a gig per second and beyond. Multipoint communication channels (one-to-many and many-to-many) are necessary for applications such as video and voice. This requires a signaling and control system that supports a multipoint call model, where a call may include multiple virtual circuits, each with its own individual characteristics. Certain applications place extreme demands on signaling systems.

Layer-specific functionality is now an important role of a switch. When ordering a switch, you now have to determine whether you only want layer 2 or whether layer 3 will be needed. Many switches have the capacity to install software to allow layer 3 capabilities; however, some layer 3 capabilities are tied to the hardware. The author's favorite layer 3 function is IP multicast through Internet Group Multicast Protocol (IGMP) snooping. IGMP snooping with proxy reporting actively sifts IGMP packets in an effort to reduce the amount of load the router is carrying that provides the multicast. When a join leaves and heads to the next routers, routes are filtered so that the smallest number of information is transported. A switch warrants that the router has one point to contend with, no matter how many listeners are out there in the network. The router is only aware of the most recent member who joined the group. Since a switch creates the layer 1 connection, both virtually and physically, it is no longer required to have systems interconnected to the same hardware or at the same physical location.

Several switches will meet an organization's needs, and several designs are available to fit in any data center or server room. Some switches, usually just in the home or small office setting, are not rackable and can be located on a desktop or server. Rack-mounted switches are intended to be used in racked environments and can range anywhere from 1 u to an entire cabinet of 42 u (u is the measurement relating to units). A chassis switch, as seen in Figure 60.1, is one that has either vertical or horizontal blades that allow for hot swapping and many different, custom options. There are many switch management features:

- Bandwidth and duplex settings for circuits
- Priority settings for ports

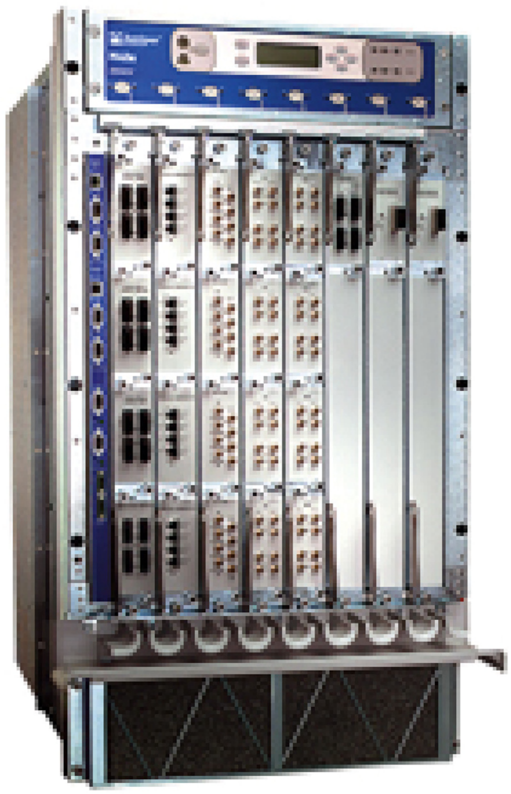

FIGURE 60.1 Chassis switch.

- Simple Network Management Protocol (SNMP) configuration to monitor devices and perform health checks
- Message authentication code (MAC) filtering and port security
- Link aggregation for versions < Elastic Sky X interface (ESXi) 5, trunking for versions of ESXi > 5
- Layer 2 and Layer 3 virtual local area network (VLAN)

Switching over to routers (no pun intended), we find that when choosing a router it is important to understand the job the router should perform. Just as there are many protocols, there are many types of routing platforms to accomplish services at the edge, at the distribution layer, or at the core. An edge router operates at the edge of a multiprotocol switching network. In a (MPLS) domain, IP datagrams are forwarded, and routing information is used to determine which labels should accompany the datagram. The packets are then labelled accordingly, and the labeled packets are forwarded into the MPLS domain.

Similarly, an edge router can strip the label and forward the resulting packet over utilizing standard IP forwarding logic. Distribution routers can aggregate traffic from multiple-access routers and are not dependent on site location or geographical region. Often, distribution

routers are responsible for enforcing quality of service (QoS) across a (WAN), so they may have considerable amounts of memory installed, multiple wide area network (WAN) interfaces, and extensive on-board data processing routines. These types of routers are also capable of providing connectivity to large groups of servers, whether it be file servers or additional external networks. Core routers operate on the Internet backbone at an organization to transmit lightning fast speeds and to forward IP packets just as fast. Routing also needs to be done at the core level, in some instances, and differs since edge routers have different features and sit at the edge of a network. Conversely, core routers can sit at the edge of a network if the engineer desires to build the infrastructure this way.

Ports and Protocols

Between the protocols User Datagram Protocol (UDP) and Transmission Control Protocol (TCP), there are 65,535 ports available for communication between devices. Among this impressive number are three classes of ports:

1. Well-known ports: Range from 0–1,023
2. Registered ports: Range from 1,024–49,151
3. Dynamic/Private ports: Range from 49,152–65,535

Understandably, not all of the ports listed in those three categories are secure. As a result, reference Table 60.1, which enumerates the most commonly used ports and the service/protocol that utilizes the port.

Ideally, when architecting a system, one should plan out the intent for the environment and should only configure the services necessary for the network to pass traffic and servers to perform their intended functions.

Table 60.1 reflects protocols that may be open by default, as well as some that are necessary for the intended purpose of the environment. When installing equipment in Section I, it is imperative that the engineer be aware of the ports that need to be open for each device or piece of software and, if needed, can be referenced in the device white paper. It is also essential to recognize the variation between the numerous types of attacks and the respective ports on which such attacks would be executed. It is necessary to monitor the ports that are open in an effort to detect protocols that may leave the network vulnerable. Running netstat on a workstation will allow one to view the ports that are running and that are open. In addition, running a local port scan will also portray which ports are exposed.

Many protocols may still be used during an installation where system administrators and users are not aware, and those may leave the network vulnerable. Simple Network Management Protocol (SNMP) and Domain Naming Service (DNS) were deployed years ago, yet still present security risks. SNMP can be utilized for monitoring the health of network equipment, servers, and other peripheral

TABLE 60.1 Well-Known Port Numbers and Their Respective Service Description and Protocol.

Port	Service/Protocol
7	Echo/TCP & UDP
9	Systat/TCP & UDP
15	Netstat/TCP & UDP
20	FTP data transfer/TCP
21	FTP control/TCP
22	SSH/TCP
23	Telnet/TCP
24	Private mail/TCP & UDP
25	SMT{/TCP
39	RLP/TCP & UDP
42	ARPA/TCP & UDP
42	Windows Internet Name Service/TCP & UCP
43	WHOIS/TCP
49	TACACS/TCP & UDP
53	DNS/TCP & UDP
69	TFTP/UDP
80	HTTP/TCP
88	Kerbos/TCP & UDP
101	NIC hostname/TCP
110	POP3/TCP
115	SFTP/TCP
119	Network News Transfer Protocol/TCP
123	NTP/UDP
143	IMAP/TCP
152	Background File Transfer Protocol/TCP & UDP
156	SQL Service/TCP & UDP
161	SNMP/UDP
162	SNMPTRAP/TCP & UDP
175	VMNET/TCP
179	BGP/TCP
220	IMAP/TCP & UDP
264	Border Gateway Multicast Protocol/TCP & UDP
280	http-mgmt/TCP & UDP
389	LDAP/TCP & UDP
443	HTTPS/TCP
500	Internet Security Assoc and Key Mgmt (ISAKMP)/UDP

equipment. However, susceptibilities associated with the SNMP derive from use of SNMP v1. Although such vulnerabilities were raised years ago (about 10 years), exposures are still reported while utilizing the current version of SNMP. Liabilities allow for authentication evasion and execution of proprietary code when utilizing SNMP. The SNMP infrastructure has three components:

1. SNMP managed connections
2. SNMP instruments
3. SNMP network management servers

Where the devices are concerned, they load the agent, which in turn assembles information and forwards it to the management servers. Network management servers collect a substantial amount of significant network information and are possibly targets of attacks due to their use of SNMP v1, which is not secure. A community name is a point of security; however, it may be similar to a password. Usually, the community name is public and is not secure, nor is it changed, thus permitting information to leak out to invasions. Conversely, SNMP v2 uses Message Digest Version 5 (MD5) for authentication. The transmission can also be encrypted. SNMP v_3 is used across firms as the criteria; however, a number of devices are not compatible and are left to use SNMP v1 or SNMP v2.

SNMP assists spiteful users to learn too much about a system, making password speculations easier. SNMP is often disregarded when checking for vulnerabilities due to the User Datagram Protocol (UDP) ports 161 and 162. Ensure network management servers are physically secured and secured on the network layer. Consider utilizing a segregate management subnet, protecting it by using a router with an access list. Unless the service is required, it should be shut off by default. In order to defend a network infrastructure from incidents aimed at obsolete or unfamiliar ports and/or protocols, remove any unnecessary protocols while creating access-control lists to allow traffic on defined ports. This eliminates the possibility of any obscure protocols being utilized, while minimizing the danger of an incident.

Threats

Hijacking occurs when an intruder takes control of a session between a server and the client. The communication starts when a middle-man attack adds a request to the client, resulting in the client getting kicked off the session. Meanwhile, the rogue workstation talks with the server, and the attacker intercepts the source-side packets, replacing them with fresh packets that are sent over to the destination. This type of hijacking, referred to as TCP/IP hijacking, most commonly occurs during telnet and Web sessions when security is nonexistent, or lacking, and also when session timeouts are improperly configured.

During the course of a Web session, cookies are commonly used to authenticate and track users. While the authentic session is in session, an attacker may attempt to hijack a session by loading a modified cookie in the session page. Session hijacking may also ensue when a session timeout is set to be an extended period of time; this gives an attacker a chance to hijack a session. Telnet-type plaintext connections create the ideal situation for TCP hijacking. In an instance like this, when an attacker surveys the data passing in the TCP session, the attacker can take control of the user's session; this is yet another reason why it is called session hijacking. When a user is forced to authenticate prior to allowing transactions to occur, it helps to prevent hijacking attacks. Protection mechanisms include the use of unique sequence numbers (USNs) and Web session cookies. The more unique the cookies, the harder it is to crack and hijack. Additional preventative measures for this type of attack include the use of encrypted session keys and Secure Socket Layer (SSL) encryption.

Spoofing

Spoofing is a method of providing false identity information to gain unauthorized access. This can be achieved by modifying the source address of traffic or source of information. Spoofing seeks to bypass IP address filters by setting up a connection from a client and sourcing the packets with an IP address that is allowed through the filter. Blind spoofing occurs when the attacker only sends data and only makes assumptions of responses. Informed spoofing is when the attacker can participate in a session and can monitor the bidirectional communications. Services that can be spoofed are:

1. Email
2. Web
3. File transfers
4. Caller ID

Web spoofing occurs when an attacker creates a convincing, fabricated copy of an entire Web site. The fabricated Web site will appear just as a real Web site would, and it has all the pages and links. The attacker controls the fabricated Web site so that all network traffic between the user's browser and the site goes through the attacker. In the situation for email spoofing, a spammer or virus can forge the email packet information in an email so that it appears that the email is coming from a trusted host, a friend, or even your own email. When one leaves their email address at an Internet site, or exchange email with others, a spoofer may be able to use your email address as the sender address to blast spam. File transfer spoofing involves the FTP service, and FTP is sent in clear, plain text. The data can be intercepted by an attacker. The data can then be viewed and altered prior to sending it over to the receiver. These types

of attacks are intended to pull information from a network of users to accomplish a more comprehensive attack. By setting up a filter to deny traffic originating from the Internet that shows an internal network address, using the signing capabilities of certificates on servers and clients will allow Web and email services to be more secure. Using an Internet Protocol Security (IPSEC) tunnel adds more security between critical servers and their clients by preventing these types of attacks from transpiring.

Intercepting Traffic

The man in the middle attack occurs when an attacker intercepts traffic and deceives the parties at both ends into believing they are communicating with one another. An attack like this is possible due to the nature of the three-way TCP handshake process using SYNchronize (SYN) and ACKnowledge (ACK) packets. Since TCP is a connection-oriented protocol, a three-way handshake takes place when establishing a connection and when closing the session. When a session is established, the client sends a SYN request; then the server sends an ACK (sometimes referred to as SYN-ACK-ACK), completing the connection. During this process, the attacker initiates the man-in-the-middle attack by using a program that appears to be a server to the client and appears to be a client to the server. In telnet and wireless communications, this attack is common. This is a difficult attack to perform due to physical routing matters, TCP sequencing number, and speed. Since the hacker must sniff both sides of the connection simultaneously, programs have been developed to aid the attacker in order to make man in the middle easier.

If an attack is performed on an internal network, physical access to that network is mandatory. By ensuring that access to wiring closets and switches are restricted, and that they're behind locked doors, physical access becomes difficult. Once the physical segment of the network has been secured, services and resources may allow a system to be inserted into a session, so those will need to be protected. DNS can be compromised and used to redirect the initial request for service, providing an opportunity to execute the man-in-the-middle attack. DNS access needs to be restricted, allowing read-only access for anyone but administrators. By using encryption and security controls and protocols, organizations can prevent these types of attacks on their infrastructure.

Packet Capturing

Packets are captured by sniffing devices in a replay attack. Once the relevant information is extracted, packets are put back on the network. An attack such as this can be used to replay a bank transaction or other comparable types of data transfers in the hopes of replicating or changing activities, such as transfers or deposits. Protecting oneself against a replay attack will involve some type of timestamp associated with the packets, or time-valued nonrepeating serial numbers. Additionally, integrating secure protocols, such as IPSEC, prevents replays of data traffic while providing authentication and data encryption.

Denial of Service

When resources have been disrupted or services that a user would expect to have access to are compromised, they have experienced a denial-of-service attack. These types of attacks are executed by manipulating protocols and can occur without the need to be validated by the network. An attack will usually involve flooding the listening port on a machine with packets. The purpose is to make that workstation so busy processing the new connections that it cannot process legitimate service requests. Several tools are available on the Internet that will produce a denial-of-service attack. IT administrators use them daily to test connectivity and troubleshoot issues on their networks, whereas malicious users will use the tool to cause connectivity issues. Some examples of DoS attacks are:

- SYN flood—This attack takes advantage of the TCP three-way handshake. A source system will send a flood of synchronization (SYN) requests and will never send the final acknowledgment (ACK), creating partially open TCP sessions. Since the TCP stack waits before resetting the port, the attack overflows the destination workstation connection buffer, making it impossible to service requests from valid users.
- Ping flood—This attack attempts to block service or reduce activity on a host by sending ping requests directly to the target. Variations of these attacks include the ping of death, where the packet size is too large and the system is unable to handle the number of packets.
- Ping/Smurfing—This attack is based on the Internet Control Message Protocol (ICMP) echo reply function. The common name is ping, the command line tool utilized to invoke the function. The attacker sends ping packets to the broadcast address of a network, replacing the original source address in the ping packets with the source address of the target, causing a flood of traffic to be sent to the unsuspecting network device.
- Fraggle—This attack is similar to smurfing. The difference is that fraggle uses UDP rather than ICMP. The attacker sends spoofed UDP packets to broadcast addresses, just as the smurf attack does. These UDP packets are directed to port 7, echo, or port 19, Chargen. When connected to port 19, a character generator attack can be run. Refer to Table 60.1 for the commonly exploited ports.
- Land—This attack exploits a behavior in the operating systems of several versions of Windows, Unix, Mac, and Cisco IOS with respect to their TCP/IP stacks. The

attacker spoofs a TCP/IP SYN packet to the victim system with the same source and destination IP address and the same source and destination ports. This confuses the system as it attempts to respond to the packet.
- Teardrop—This form of attack targets a known behavior of UDP in the TCP/IP stack of some operating systems. The Teardrop attack will send fragmented UDP packets to the target with odd offset values in subsequent packets. When the operating system attempts to rebuild the original packets from the fragments, the fragments overwrite each other, causing confusion. Since some operating systems cannot elegantly handle the error, the system will either crash or restart.

DoS attacks come in many flavors, shapes, and sizes. Take the first step to protect the firm from an attack: Understand the types of attacks and the nature in which they operate.

Distributed Denial of Service

A modest expansion of denial of service can be referred to as distributed DoS attacks. Masters are computers that run the client software, where zombies will run the software. The attacker will create a master, which in turn creates a large number of zombies, or recruits. The software that runs on the zombies can launch multiple types of attacks, such as UDP or SYN flooding on a particular target. Figure 60.2 depicts a distributed DoS attack.

Although distributed DoS attacks usually come from the outside of the network to deny services, the impact of the attacks displayed inside the network should also be cogitated. Internal distributed DoS attacks allow disgruntled employees or malicious users to disrupt services without any outside influence or interaction. To help protect your network, set up filters on external routers to drop packets involved in these types of attacks. Also, set up an additional filter that denies traffic originating from the Internet but showing an internal IP address. By doing this, ping and some services are lost to test network connectivity, but this is where administrators should be on a separated network segment than users and would be on a segment where the filtering did not occur. If the operating system supports it, one can reduce the amount of time before the reset of an unfinished TCP connection. Doing so makes it harder to keep resources unavailable for extended periods of time.

Tip: In the case of a distributed DoS attack, it is best to get in touch with your service provider so that they can divert traffic or block traffic at a higher level.

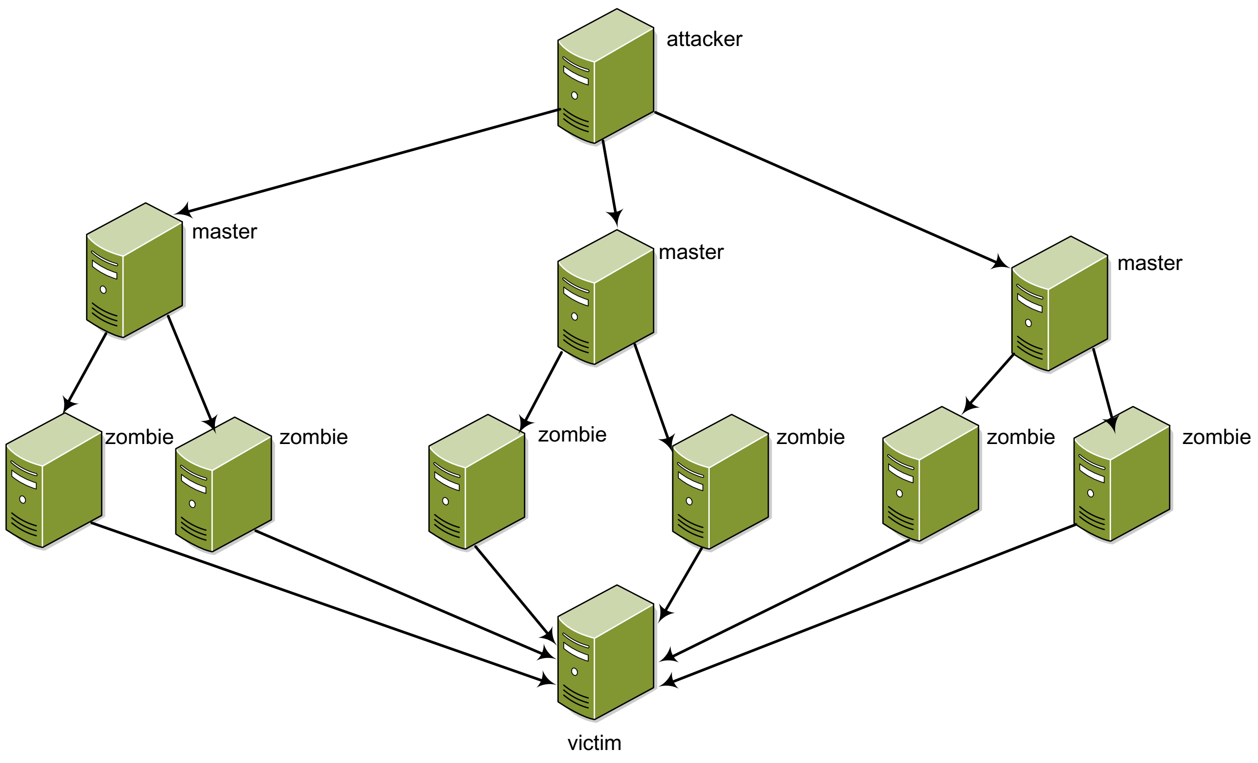

FIGURE 60.2 Distributed denial-of-service attack.

ARP Poisoning

Every network card has a 48-bit address that is unique and hard-coded into the card. For network communications to occur, this hardware address must be associated with an IP address. Address resolution protocol (ARP), which operates at layer 2 (data link layer) of the Open System Interconnection (OSI) model, associates MAC addresses to IP addresses. ARP is a lower-layer protocol that is straightforward and consists of requests and replies without validation. However, this simplicity leads to a lack of security.

When using a protocol analyzer to look at traffic, you will see an ARP request and an ARP reply, which are the two fundamental parts of ARP communication. There are also reverse ARP (RARP) requests and RARP replies. Devices maintain an ARP table that contains a cache of the IP addresses and MAC addresses that the device has already correlated. The host device searches its ARP table to see whether there is a MAC address corresponding to the destination host IP address. When there is no matching entry, it broadcasts an ARP request to the entire network. The broadcast is seen by all systems, but only the device that has the corresponding information replies. However, devices can accept ARP replies before even requesting them. This type of entry is known as an unsolicited entry because the information was not explicitly requested.

Because ARP does not require any type of validation, as ARP requests are sent, the requesting devices believe that the incoming ARP replies are from the correct devices. This can allow a perpetrator to trick a device into thinking any IP is related to any MAC address. In addition, they can broadcast fake or spoofed ARP replies to an entire network and attack all computers. This is known as ARP poisoning. Simply worded, the attacker deceives a device on your network, poisoning its table associations of other devices.

ARP poisoning can lead to attacks such as denial of service, man in the middle, and MAC flooding. Denial of service and man in the middle were discussed earlier in this chapter. MAC flooding is an attack directed at network switches. This type of attack is successful because of the nature of the way all switches and bridges work. The amount of space allocated to store source addresses of packets is limited. When the table becomes full, the device can no longer learn new information and becomes flooded. As a result, the switch can be forced into a hub-like state that will broadcast all network traffic to every device in the network. Macof is a tool that floods the network with random MAC addresses. Switches may get stuck in open repeating mode, leaving the network traffic susceptible to sniffing. Nonintelligent switches do not check the sender's identity, thereby allowing this condition to happen.

A lesser vulnerability of ARP is port stealing. Port stealing is a man-in-the-middle attack that exploits the binding between the port and the MAC address. The principle behind port stealing is that an attacker sends numerous packets with the source IP address of the victim and the destination MAC address of the attacker. This attack applies to broadcast networks built from switches. ARP traffic operates at layer 2, the data link layer of the OSI model, and is broadcast on local subnets. ARP poisoning is limited to attacks that are local, so an intruder needs either physical access to your network or control of a device on your network. To mitigate ARP poisoning on a small network, you can use static or script-based mapping for IP addresses and ARP tables. For larger networks, utilize equipment that offers port security. By doing so, one can only permit one MAC address for each physical port on the switch. In addition, you can deploy monitoring tools or an intrusion detection system (IDS) to signal when suspicious activity occurs.

DNS Poisoning

DNS poisoning enables a perpetrator to redirect traffic by changing the IP record for a specific domain, thus permitting the attacker to send legitimate traffic anywhere he chooses. This not only sends a requestor to a different Web site, but also caches this information for a short period and distributes the attack's effect to the servers users. DNS poisoning may also be referred to as DNS cache poisoning because it affects the information that is cached.

Because all Internet requests begin with a DNS query, if the IP address is not known locally then the request is sent to a DNS server. There are two types of DNS servers: authoritative and recursive. DNS servers share information, but recursive servers maintain information in their cache. This means caching or recursive servers can answer queries for resource records even if they cannot resolve the request directly. A flaw in the resolution algorithm allows the poisoning of DNS records on a server. All an attacker has to do is delegate a false name to the domain server along with providing a false address for the server. For example, an attacker creates a hostname hackattack.gov. Next, the attacker queries your DNS server to resolve the host hackattack.gov. The DNS server resolves the name and stores the information in its cache. Until the zone expiration, any further requests for hackattack.gov do not result in lookups but are answered by the server from its cache. It is now possible for the attacker to set your DNS server as the authoritative server for the zone with the domain registrar.

If the attacker conducts malicious activity, the attacker can make it appear that your DNS server is being used for those malicious activities.

DNS poisoning can result in many different implications. Domain name servers can be used for distributed DoS attacks. Malware can be downloaded to an unsuspecting user's computer from the rogue site, and all future requests by that computer will be redirected to the fake IP address. This could be used to build an effective botnet. This method of poisoning could also allow for cross-site scripting exploits, especially since Web 2.0 capabilities allow content to be pulled from multiple Web sites simultaneously.

To minimize the effects of DNS poisoning, check the DNS setup if you are hosting your own DNS. Be sure the DNS server is not open-recursive. An open-recursive DNS server responds to any lookup request, without checking where the request originated. Disable recursive access for other networks to resolve names that are not in your zone files. Also, use different servers for authoritative and recursive lookups and require that cached information is discarded except from the com servers and the root servers. As far as users are concerned, educate them. However, it is becoming increasingly difficult to spot an issue by watching the address bar on an Internet browser. Therefore, operating system vendors are adding more protection by notifying the user that a program is attempting to change the system's settings, thus preventing the DNS cache from being poisoned.

2. ATTACKS AND COUNTERMEASURES

To secure a network, a firewall can be successfully implemented and utilized whether it is software or hardware based. The purpose of a firewall is to control the incoming and outgoing traffic by analyzing packets and determining whether or not a rule set will allow the traffic in or not.

Network Firewall

In Figure 60.3, the firewall is protecting the network, rather than leaving it directly exposed to the Internet. The firewall will sit in conjunction with a network device and will serve as a gateway between two networks.

Firewalls inspect all traffic routed between two networks to determine whether or not that traffic meets predetermined criteria. If it does, the traffic is allowed through and routed to the appropriate destination. Otherwise, the traffic is blocked. Firewalls can also manage public access to private network resources, such as host applications. Hard drive space on firewalls is becoming increasingly important since log entries can grow to be terabytes of data, depending on the amount of traffic on your network. Consider your logging setup to log every attempt to enter into and exit the network. When half the company is surfing the Internet during their lunch time, one can fathom how large the log files can grow to be. Firewalls can also filter packets specific to network types and is known as protocol filtering. Since the decision to forward or reject traffic is dependent on the protocol used, a user attempting to access a server via HTTP, FTP, or telnet will either be allowed or denied based not only on their access to the server, but also on whether the firewall allows specific protocol access to that target server.

Firewalls use two approaches: Allow all traffic unless said traffic meets a certain criteria or deny all traffic unless it meets a certain criteria. Additionally, firewalls can fit into four categories: packet filters, circuit-level gateways, application-level gateways, and stateful multilayer inspection firewalls. Packet filtering firewalls sit at the Network Layer, or the IP layer of the TCP/IP Layer. Depending on the packet criteria, the firewall can drop the packet, forward it, or send a message to the initiator. Rules can include source and destination IP address, source and destination port number, and protocol used. The advantage of packet filtering firewalls is that they are affordable and have no impact on network performance. If a higher level firewall is used, packet filtering rules will not add any overhead to the network traffic. A lower level firewall will not support many other features that an organization may desire, such as network address translation (NAT). NAT is used in many different types of companies, whether it is a trading firm or a law firm. Understanding private and public IP addressing is the

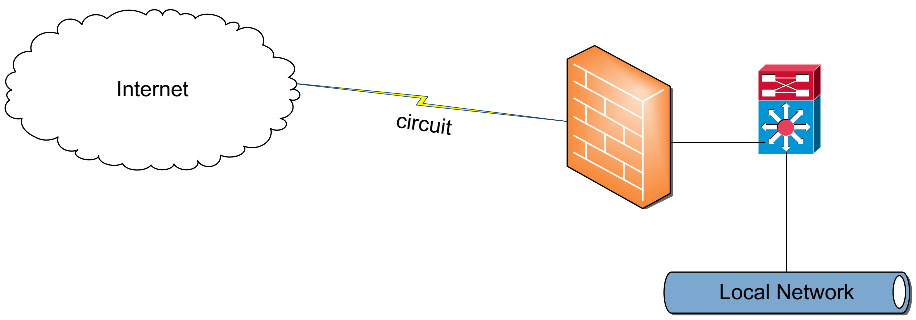

FIGURE 60.3 A firewall is placed between the outside world and the internal local network components.

first step in translating network addresses. Your internal network will communicate with internal IPs; however, if you have a client that needs to access a server on your network, giving them the internal IP on your network will not allow them access unless they're on your virtual private network (VPN). So, translating that IP to a public IP will allow the user to access that internal server, but the firewall is the tool that gives the user outside access by translating the IP. Additionally, the firewall needs to know that 66.55.44.123 is a public IP that belongs to internal IP 10.10.10.100. How will the user access the server? If a user wants to RDP to 10.10.10.100, the firewall must give RDP access to that server. Specific ports and protocols are allowed at the firewall level, too. When implementing a firewall, one must consider the following measures:

- Determine the access denial methodology: Most recommend denying all access by default right at the start. That would have a gateway that routes no traffic and is a brick wall with no doors in it. If you prefer a solid, secure environment, this is the first step, and then you can allow access from here.
- Determine inbound access: If all of your Internet traffic originates on the LAN, a NAT router will block all inbound traffic that is not in response to requests originating from within the LAN. As mentioned in the preceding example, only the external IP address is given to a client. The internal IP addresses of hosts behind the firewall are never revealed to the outside world, which makes intrusion difficult. Most hosts are nonpublic IPs, so it would make it difficult unless the attacker was on the internal network; however, it is the best practice. Packets coming in from the Internet in response to requests from local hosts are addressed to dynamically allocate port numbers on the public side of the NAT router. These numbers change rapidly, making it nearly impossible for an intruder to make assumptions of which port number they could use. You may also want to determine which criteria can be used when a packet originates from the Internet and whether or not to allow it into the LAN. The more rigorous the rules, the more secure your network will be. Ideally, you'll know which public IP addresses on the Internet originate inbound traffic, and by limiting inbound traffic to packets originating from specific hosts, you decrease the likelihood of hostile intrusion. Going further, earlier protocols were mentioned, and limiting communication-based off-protocol sets like HTTP or FTP adds greater security.
- Determine outbound access: When users only need access to the Internet, a proxy server may provide enough security, with access granted based off user rights. This type of firewall can be a great deal to manage since it requires manual configuration of each Web browser on every machine. Outbound protocol filtering can also be transparently achieved with packet filtering and no sacrifice on security. If you are using NAT without inbound mapping or traffic originating from the Internet, then it is possible to allow users access to all services on the Internet without compromising security. Consequently, there is a risk of employees acting irresponsibly through email or external hosts, but that is a management or HR issue and not IT.

Proxies

Proxy servers are capable of functioning on dedicated hardware or as software on a utility server. It acts as a transitional point of communication between two clients attempting to reach out to other servers. For example, if a client connects to a proxy server, requesting some file or connection, the proxy server will assess the request in an effort to simplify and regulate the intricacy of the communication, as shown in Figure 60.4.

Proxies can perform just as a firewall would by handling connection requests for packets coming into an application and by blocking any other packets. A proxy server can be thought of as a gateway from Network A to a certain network application, while acting as a proxy for the user on the network. When an administrator properly designs the function of a proxy, it is much more difficult for an outside attacker to access the internal network. However, an attacker may utilize a highly available system and use it as a proxy for their selfish means. This allows the proxy to deceive other machines, forcing them to think the proxy is safe and on their network, or their proxy. Utilizing internal, private IP addresses adds another layer for security; conversely, hackers could spoof the IP's attempt to gain access and transmit packets to a network.

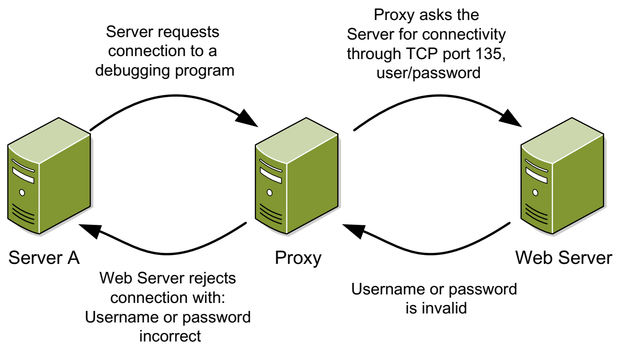

FIGURE 60.4 Communication between two servers connecting through a proxy, the third server.

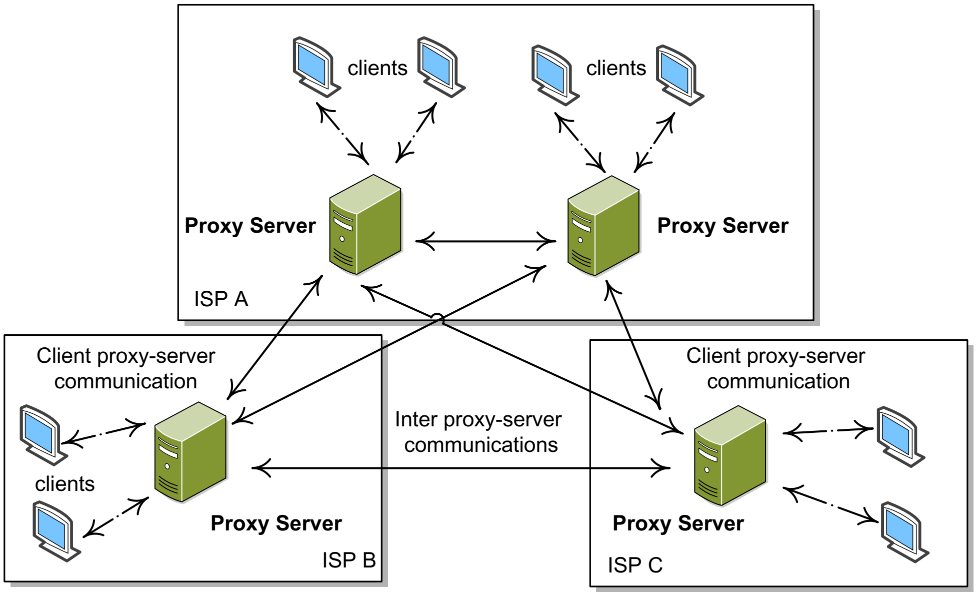

FIGURE 60.5 One session using the proxy server model.

Proxy servers have become prevalent in the gaming community since real-time, Internet gaming surfaced. Considering how many kids and adults are into gaming, the network for real-time streaming multiplayer gaming requires a low-latency proxy server-network topology. Client-server or peer-to-peer topologies provide a variety of positive aspects and can be applied intricately, leading to their high acquiescence for computer gaming. Both models also have many disadvantages, which results in weak QoS and constrains robust gaming architectures where there are a high amount of users. As soon as the player numbers increase, client-server and peer-to-peer topologies do not scale well. Additionally, the server in a client-server framework forms a single point of failure for the entire session. While the peer-to-peer method eradicates the problem of a single point of failure, a hacked client can cheat, since acquiesced game updates are not filtered by a server instance and concealed information becomes readily available to the player.

Architecting a proxy server setup, stemming from a peer-to-peer server-network, is shown in Figure 60.5. Utilizing several interconnected proxy servers for a one-user gaming session shows each proxy server having a full view of the comprehensive game architecture. Each client communicates with a single proxy, sending user selections and obtaining updates of the game status.

Proxy servers process user actions and forward them to other proxies, manipulating multicast at the IP or application level to synchronize the disseminated game state. With regard to low-latency Internet-centered sessions, proxy servers need to be disbursed among different Internet service providers (ISPs), such that each client will connect to a proxy at its local ISP. Through testing, the author has set up the servers manually; however, testing proves that a dynamic setup of proxies falls in line with user demand and quick response times. Rather than replicating a gaming world, one could partition the approach across servers, compelling clients to exchange servers depending on their region. This approach may work well to accommodate slower flow of traffic, but it cannot be applied to the low-latency, graphic-intensive world. Pauses are annoying for users, as are noticeable server changes. Because the proxy has a wide spectrum to view the game state, best practices avoid a proxy server-network to attempt multiple reconnects during one session.

To manage replication utilizing proxy servers in a gaming infrastructure, ensure that the architecture is scalable, responsive, and consistent, simulating large amounts of data. Although trade-offs may be involved, implementing strong consistency patterns will increase the amount of inter-proxy communication. For example, proxies would order changes of the game state using timestamps or a physical clock mechanism. This would delay the transmission of acknowledgments of user actions to clients, thus reducing the responsiveness of the game. Talk about detrimental; especially when you've stood in line for 18 hours outside of the store, and now you're competing with 500,000 other users during the first hour of the game. A scalable, distributed model with real-time performance can only be achieved

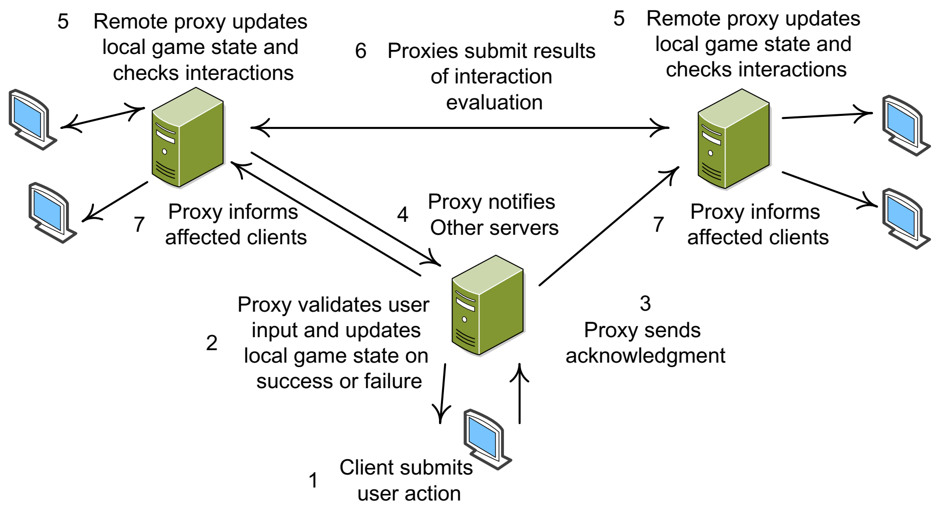

FIGURE 60.6 A user performing a single action—acknowledging and forwarding an action.

if all the servers do not talk to each other simultaneously; nonetheless, servers must be able to share the same data at all times. To implement this architecture, only allow one process to alter specific parts of replicated data (shown in Figure 60.6). Changes must be propagated to other processes, certifying the reliability of the replicated state immediately as the message arrives. The process in Figure 60.6 can be described by following these steps: (1) user actions are transferred from clients; (2) the server checks to see if the input is authorized to block cheating before changing the state; (3) consistency for the altered part of the game state is guaranteed, and the clients receive acknowledgments for movement commands in a short amount of time; (4) informs proxies about updating position values; (5) update local copies consequently; (6)in the case of interactions, notified proxies also check whether local clients are affected, and if local clients are affected, the proxy updates the game state of its local client and informs other servers; and (7) for all state updates received from other proxy servers, each proxy evaluates which local clients are affected and informs them. The architecture presented allows for management of a distributed state, with efficient synchronization of the game state in conjunction with fast acknowledgment of user actions.

3. SUMMARY

This chapter focused on how security is presented to protect the infrastructure. Smart grid cybersecurity must address not only deliberate attacks, such as from disgruntled employees, industrial espionage, and terrorists, but also inadvertent compromises of the information infrastructure due to user errors, equipment failures, and natural disasters.

Infrastructure Security Tasks Checklist

The primary intent of this chapter is to increase your awareness of specific technologies that secure the foundation of your infrastructure. Although this part of the chapter is called a checklist, each of the tasks in the checklist (An Agenda for Action for Implementing Infrastructure Security Tasks) requires so much elaboration that it is easy to lose the thread of organization. The guiding structure is to first summarize the major types of security vulnerabilities and mitigation techniques in general, and then traverse the OSI communication reference model layers (previously discussed) while discussing specific security considerations.

This chapter also addressed the critical cybersecurity needs in the areas of encryption key management, security requirements, testing criteria for remote upgrades, and privacy recommendations for third-party data usage. The chapter also provided foundational cybersecurity guidance, outreach, and foster collaborations in the cross-cutting issue of cybersecurity in the smart grid. Remember that a system is only as secure as its most vulnerable path, and it is difficult (if not impossible) to build a secure voice solution if the infrastructure foundation is insecure.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

An Agenda for Action for Implementing Infrastructure Security Tasks

Please see the following infrastructure security tasks (check all tasks completed):

Infrastructure security tasks are designed to thwart several types of threats:

_____**1.** Unauthorized traffic types going where they should not go (unauthorized access and denial of service).

_____**2.** Authorized traffic types using more bandwidth or other resources than they should (denial of service).

_____**3.** Unauthorized devices mimicking authorized devices (violating integrity).

_____**4.** Unauthorized devices intercepting communications intended for other devices (violating privacy).

At the infrastructure level, these threats are thwarted by:

_____**5.** Securing the routers and switches themselves so that they continue to perform their packet/frame forwarding and filtering functions.

_____**6.** Keeping unauthorized devices from being in the communication path by using filters and security mitigation features at different layers of the protocol stack and protecting against frame forgery and spoofing attempts to bypass the filters.

Filters that operate at most layers of the protocol stack under various feature names are appropriate at the following points in the network:

_____**7.** Ingress directly on hosts, servers, or endpoint devices (considered separately under host hardening, as opposed to infrastructure security features). (*Note:* This is distinct from filters that you can apply on Ethernet switches or other networking gear.)

_____**8.** Ingress Ethernet ports in wiring closet switches, where traffic first enters a network.

_____**9.** IP subnet boundaries where traffic crosses between VLANs.

_____**10.** Boundaries between network segments that are in different administrative domains

The following protocols that form the core of IP network functionality are critical components to consider as candidates for spoofing attacks:

_____**11.** Ethernet frame headers that contain source/destination link layer addresses.

_____**12.** IP packet headers that contain source/destination network layer addresses.

_____**13.** Address Resolution Protocol (ARP), which binds permanent Ethernet hardware addresses to configuration-specific IP logical addresses.

_____**14.** Dynamic Host Configuration Protocol (DHCP), which automatically assigns IP addresses to devices.

_____**15.** Domain Name Service (DNS), which maps human-readable names to IP addresses.

_____**16.** Hot Standby Router Protocol (HSRP), which provides a single virtual Ethernet hardware address and IP address for a group of routers that provide redundant default gateway services.

_____**17.** IEEE 802.1d Spanning Tree Protocol (STP), which controls the layer 2 Ethernet frame forwarding behavior in a switched Ethernet LAN or metropolitan area network (MAN).

_____**18.** IEEE 802.1q Ethernet trunk interfaces, which let a single physical Ethernet port share multiple VLANs.

_____**19.** Virtual Trunking Protocol (VTP) and other control protocols, which switch use to exchange VLAN configuration information.

_____**20.** Routing protocols that control the layer 3 packet forwarding behavior in a network.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Since the inception of technology, data security revolves around cryptography.
2. True or False? Cipher text and secret keys are transported over the network, and can be harvested for analysis, and furthermore to impersonate a source or, in a worst case, cause a service acceptance.
3. True or False? Backbone networks require switches with tremendous capacity.
4. True or False? Between the UDP and TCP protocols, there are 5,535 ports available for communication between devices.
5. True or False? Hijacking occurs when an intruder takes control of a session between a server and the port.

Multiple Choice

1. What is a method of providing false identity information to gain unauthorized access?
   - **A.** Qualitative analysis
   - **B.** Vulnerabilities
   - **C.** Spoofing
   - **D.** Misconfiguration
   - **E.** DHS
2. What attack occurs when an attacker intercepts traffic and deceives the parties at both ends into believing they are communicating with one another?
   - **A.** Firewall
   - **B.** Risk assessment
   - **C.** Scale
   - **D.** Man in the middle
   - **E.** Bait

3. What are captured by sniffing devices in a replay attack?
   A. Organizations
   B. Fabric
   C. Packets
   D. Web application firewall
   E. Security
4. When resources have been disrupted or services are compromised that a user would expect to have access to, they have experienced a:
   A. cabinet-level state office
   B. denial-of-service attack
   C. hardening
   D. SAN protocol
   E. taps
5. A modest expansion of denial of service can be referred to as:
   A. systems security plan
   B. consumer privacy protection
   C. IP storage access
   D. vulnerability
   E. distributed denial of service attacks

EXERCISE

Problem

Which Ethernet ports require 802.1*x* authentication?

Hands-On Projects

Project

What 802.1*x* authentication mechanism should one use?

Case Projects

Problem

Do all clients support 802.1*x*?

Optional Team Case Project

Problem

Does 802.1*x* have security vulnerabilities?

Chapter 61

Access Controls

Lauren Collins
kCura Corporation

1. INFRASTRUCTURE WEAKNESSES: DAC, MAC, AND RBAC

The dichotomy between types of companies and implementing layers of security led to the use of three types of access control mechanisms: discretionary access control, mandatory access control, and role-based access control.

Discretionary Access Control

Discretionary access control (DAC), also known as file permissions, is the access control in Unix and Linux systems. Whenever you have seen the syntax drwxr-xs-x, it is the ugo abbreviation for owner, group, and other permissions in the directory listing. Ugo is the abbreviation for user access, group access, and other system user's access, respectively. These file permissions are set to allow or deny access to members of their own group, or any other groups. Modification of file, directory, and devices are achieved using the chmod command. Tables 61.1 and 61.2 illustrate the syntax to assign or remove permissions. Permissions can be assigned using the character format:

```
Chmod [ugoa] [+ − = ] [rwxXst] fileORdirectoryName
```

In DAC, usually the resource owner will control who access resources. Everyone has administered a system in which they decide to give full rights to everyone so that it is less to manage. The issue with this approach is that users are allowed not only to read, write, and execute files, but also to delete any files they have access to. This author has so often seen system files deleted in error by users, or simply by the user's lack of knowledge. This is an instance where DAC could be seen as a disadvantage, or less advantageous.

TABLE 61.1 Notation to Add, Remove Access, and how to Explicitly Assign Access.

+	add access
−	remove access
=	access explicitly assigned

TABLE 61.2 Notation for File Permissions.

r	Permission to read file
	Permission to read a directory (also requires '*x*')
w	Permission to delete or modify a file
	Permission to delete or modify files in a directory
x	Permission to execute a file/script
	Permission to read a directory (also requires '*r*')
s	Set user or group ID on execution
u	Permissions granted to the user who owns the file
t	Set sticky bit. Execute file/script as a user root for regular user

Mandatory Access Control

Mandatory access control (MAC) regulates user process access to resources based on an organizational security policy. This particular policy is a collection of rules that specify what types of access are allowed on a system. System policy is associated with MAC comparably to how firewall rules are associated with firewalls. Security-enhanced Linux (SELinux) is a Linux kernel implementation of a supple MAC mechanism called type enforcement. These policies restrict users and processes to the minimal amount of privilege required to perform tasks. Type enforcement uses a type identifier and assigns it to every user and object; these authorizations are defined in a SELinux policy.

The SELinux implementation of MAC exercises a type of enforcement mechanism that necessitates every

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00061-1

subject and object be assigned an identifier. We will use the terms *subject* and *object* for this example. Consider the subject as a user or a process, and the object as a file or a process. Characteristically, a subject cannot access an object unless the type identifier assigned to the subject is authorized to access the object. The default policy is to deny all access that is not specifically allowed. Authorization is determined by rules defined in the SELinux policy. The following is an example of rule-granting access:

```
allow httpd_t httpd_sys_content_t : file (ioctol
read getattr lock);
```

where the subject http daemon is assigned the type identifier of httpd_t and is granted permissions ioctol, read, gettattr, and lock for any file object assigned in the type identifier httpd_sys_content_t. Basically, the http daemon is allowed to read a rule that is assigned the type identifier httpsd_sys_content_t. This is a simpler rule; there are thousands of rules, varying in complexity. There are also many types of identifiers for use with subjects and objects. SELinux adds type enforcement to standard Linux distributions. To access an object, the user must have both the appropriate file permissions (DAC) and the correct SELinux access. ELinux security context covers three capacities:

1. The user
2. The role
3. The type identifier

By running the ls command with the -Z switch, conventional file information is displayed along with the security context for each element in the subdirectory. See the following example, where the security context for the index.html file encompasses user_u as the user, object_r as the role, and httpd_sys_content_t as the type identifier:

```
[web_admin@localhost html]$ ls -Z index.html
-rw-r-r- web_admin web_admin user_u:object_r:
httpd_sys_content_t index.html
```

Role-Based Access Control

Role-based access control (RBAC) is a method whereby only authorized users can gain access to an environment and the sessions contained in the environment, as shown in Figure 61.1. Some refer to RBAC as role-based security due to the roles an organization creates to assign permissions to users, who perform specific functions, and such users acquire their roles and rights when their account is created. In Active Directory, either the users are in a department that assigns rights by department or the users have customized access based off their role to perform a job function. Referring to the model in Figure 61.1, use the following conventions:

- Subject (S)—person or agent
- Role (R)—job function
- Permission (P)—authorization to access a resource or utility
- Session (SE)—mapping, including S, R, and/or P
- Subject Assignment (SA)
- Permission Agent (PA)
- Partial Instructional Role Hierarchy (RH)—$\geq$ (where $x \geq y$ requires x to inherit permissions of y)
  1. Subjects are allowed multiple roles.
  2. Roles are allowed to contain multiple subjects.
  3. Roles are allowed to assign multiple permissions.
  4. Permissions can be allocated to multiple roles.
  5. Operations can be allocated to multiple permissions.
  6. Permissions can be allocated many operations.

Whereas a constraint positions a provisional rule on the possibility of inherited permissions from contrasting rules; it can thus be utilized to attain applicable partitions of duties. As such, a user should not be permitted to both create a login or to empower such an account creation. RBAC is comprised of three principal guidelines:

1. Role assignment: A subject can implement permission once the subject has been designated or has allocated a role.
2. Role authorization: A subject's dynamic role requires permission for the subject. Refer to rule 1, above, which warrants users only inherit roles for which they are sanctioned.
3. Permission authorization: A subject can employ permission merely if the permission is approved for the subject's functional role. Refer to rules 1 and 2; rule 3 confirms users can only carry out permissions for which they are allowed.

Several additional controls can be applied on top of the former three rules, and roles can be combined in a hierarchy where higher level roles consider permissions retained by subroles. In larger organizations, typically those with over 500 users, administrators tend to combine MAC or DAC.

As previously mentioned, RBAC can be referred to as an adaptable secure access control. RBAC diverges from access control lists (ACLs) in that it appoints permissions to exclusive operations for users to perform their job functions, rather than to low-level data objects. Let's say an access control list could be utilized to allow or deny write access to a certain file system, but it is unable to dictate how that file could be changed.

As an example, in financial systems, an operation may seek to create a new trading account or to create a new database for a particular trading product. The assignment

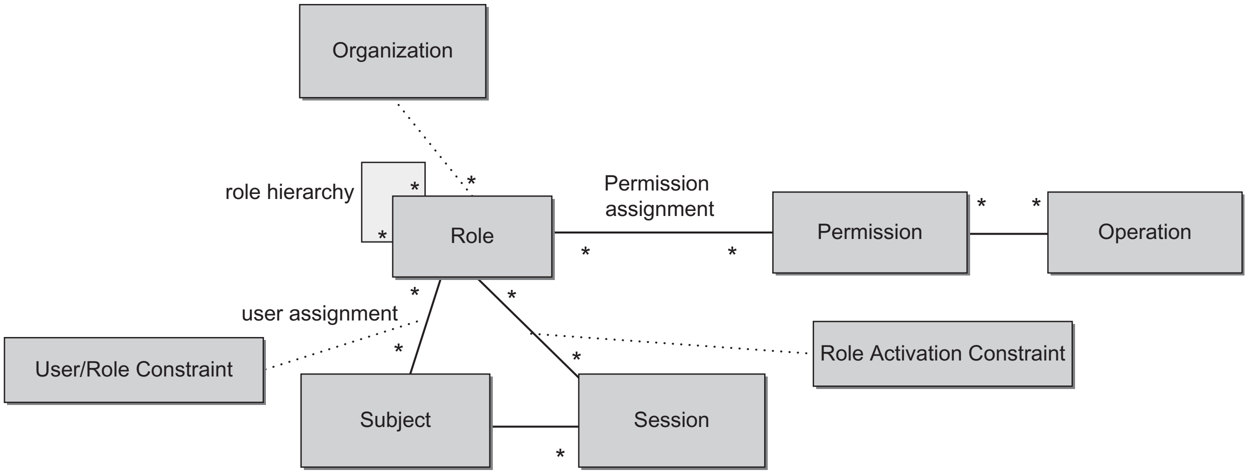

FIGURE 61.1 Role-based access control model that restricts environment access to authorized users.

of the permission to perform a particular operation is meaningful in this instance, since the operations are so granular with meaning to an application. You would not want college interns creating new trading accounts utilizing real money and would prefer that only an administrator of the risk department had those rights. Even concerning trading limits, imagine if traders could go into the application and raise their trading limits themselves. Risk controls are put into place to protect assets and rights.

RBAC is well suited to separate liabilities, ensuring that more than two people are involved in authorizing critical operations. Integrating RBAC benefits access control policies and aids the IT infrastructure where Active Directory, SQL Server, and any other proprietary applications are concerned.

Logical Access Controls

Logical access controls tools are used for credentials, validation, authorization, and accountability in an infrastructure and the systems within. These components enforce access control measures for systems, applications, processes, and information. This type of access control can also be embedded inside an application, operating system, database, or infrastructure administrative system. Physical access control is a mechanical form and can be thought of physical access to a room with a key. The line is often unclear whether or not an element can be considered physical or logical access control. Physical access is controlled by software, the chip on an access card and an electric lock grant access through software. Thus, physical access should be considered a logical access control. A benefit of having logical access controlled centrally in a system allows for a user's physical access permissions to be instantaneously revoked or amended. For example, when an employee is fired, his or her badge access can be disabled, as can the employee's multiple system access accounts. Persons in possession of the proper access card, the appropriate security level, and in some cases a pin are granted entry to a room once the credentials are checked against a database.

Physical Access Controls

Physical access control is a mechanical form and can be thought of physical access to a room with a key. The line is often unclear whether or not an element can be considered a physical or a logical access control. When physical access is controlled by software, the chip on an access card and an electric lock grants access through software (see checklist: An Agenda for Action for Evaluating Authentication and Access Control Software Products), which should be considered a logical access control. That being said, incorporating biometrics adds another layer to gain entry into a room. This is considered a physical access control. Identity authentication is based on a person's physical characteristics. The most common physical access controls are used at hospitals, police stations, government offices, data centers, and any area that contains sensitive equipment and/or data.

A significant element surrounding physical access controls as opposed to conventional security solutions is its capacity to capture multifaceted and detailed images of physical traits, encode such traits in files, and evaluate sets of data within seconds. Homeowners are now considering this layer of security since loved ones and belongings are sacred, and this layer of security is not possible to forge. Physical access controls not only enhance security but also allow for efficiency, only requiring one form of authentication, a physical trait (fingerprint, retina, palm of hand). This eliminates the risk of a card being stolen or a PIN being hacked.

An Agenda for Action for Evaluating Authentication and Access Control Software Products

Before one starts evaluating authentication and access control software products, they'll need to answer several questions about the technology; as well as the organization's specific needs (check all tasks completed):

_____1. **What needs to be protected?** The type and level of protection required depends on the assets you'll be safeguarding. After all, national security secrets need more extensive (and costly) protection than a public domain data collection. This is an important matter you will need to discuss with a security professional.

_____2. **Which type of authentication is best?** There are four basic ways of authenticating users: asking for something only the authorized user knows (such as a password), testing for the presence of something only the authorized user has (like a smart card), obtaining some nonforgeable biological or behavioral measurement of the user (like a fingerprint), or determining that the user is located at a place where only the authorized user can enter. The best (and most effective) solutions require a combination of two or more authentication methods.

_____3. **Is the software compatible with existing systems and devices?** The solution must be compatible with current operating systems and applications. Compatibility is a particularly big concern with biometric systems, since existing hardware and applications often must be adapted and/or reprogrammed to work with these tools.

_____4. **Does it offer an acceptable trade-off between security and convenience?** Organizations must balance the value of the information being protected with the authentication and access control software's ease of use. Solutions that are difficult to use may protect systems, but only at the expense of user convenience and productivity.

_____5. **How easy is it to upgrade and expand the software?** You'll want a product that you can use for many years. Over that time span, it will need to be upgraded to accommodate new security practices and technologies.

_____6. **Will the software work with other types of solutions, such as antifraud and user behavior-monitoring technologies?** These days, access control is often a part of a multifaceted enterprise security initiative. It's important to know if the software you're looking at plays well with others.

_____7. **What are the product's management features?** Authentication and access control software products are notoriously difficult to set up and maintain. Look for management features that are straightforward and easy to understand.

_____8. **Has the software ever been defeated? If so, how?** If the product has ever been hacked, you'll want to know what steps the vendor has taken to make its technology more secure.

_____9. How much does the software cost? Don't look at the license fee alone. The total product cost includes acquisition, customization, deployment, management, user training, extra hardware, productivity impact, and maintenance. Ask vendors for detailed statements, policies, and prices for each of these factors.

2. STRENGTHENING THE INFRASTRUCTURE: AUTHENTICATION SYSTEMS

Authentication might involve confirming the identity of a person or software program (see checklist: An Agenda for Action for Evaluating Authentication and Access Control Software Products). The introduction to this chapter mentioned three categories authentication may fall under. Whether it is knowledge specific to a user, a piece of information the user has, or the position the user is in, each of them aims to verify the user's identity. Each authentication factor covers a range of elements used to authenticate or verify a person's identity prior to being granted access. Examples include a computer approving a transaction request, electronically signing a document or other work product, administrators granting authority to users with management approval, and a chain of authority that must be established to keep the controls in place and consistent. Security investigations have determined that the standard for verification must include components from at least two factors, and preferably three. Three authentication factors are as follows:

1. *Ownership factors*: something tangible the user has (ID card, security token, software token, phone or cell phone)
2. *Knowledge factors*: a piece of information the user knows (password, pass phrase, PIN, or a challenge response, such as a security question only the user knows the answer to)
3. *Physical factors*: a physical trait of an individual (fingerprint, retinal pattern, signature, voice, or another biometrical identifier)

A common example of a two-factor authentication is when one uses his or her ATM card and has to enter a PIN. Some organizations not only require a username

and password to authenticate to the VPN, but also give employees a token with a random set of numbers that change every 30 seconds. The author has visited multiple data center facilities, and while some differ in their choice of the second authentication factor, all data centers require two-factor authentication. While one data center may require use of a badge and your pointer finger fingerprint, others may use a PIN along with a biometric hand scan. Additionally, a handful of facilities include a third factor for authentication, a mantrap. The mantrap screens the person's height, weight, facial features, and retina. These facilities institute higher security standards and are generally financial or governmental collocation sites.

Kerberos and CHAP

Kerberos is a secure method for authenticating a request for a service in a network. Kerberos was developed in the Athena Project at the Massachusetts Institute of Technology (MIT). Based on the name of the Needham-Schroeder protocol, Kerberos is named after a three-headed dog who guarded the gates of Hades in Greek mythology. Kerberos lets a user request an encrypted "ticket" from an authentication process that can then be used to request a particular service from a server. The user's password does not have to pass through the network. MIT offers a download for both the client and server versions of Kerberos, or you can buy a copy.

One weakness is that Kerberos requires the continuous availability of a central server. Knock out the Kerberos server and no one can log in. This problem can be mitigated by using multiple Kerberos servers. The technology is also sensitive to clock settings and won't work properly unless the clocks of the involved hosts are synchronized. Default configuration requires that clock times be no more than 10 minutes apart. Additionally, the administration of the protocol is not standardized and differs between server implementations. And since the secret keys for all users are stored on the central server, a compromise of that server will jeapardize all users' secret keys.

Big data is a hot subject these days, and without question an increasing number of enterprise information security teams are going to be asked about the security-related ramifications of big data projects. There are many issues to look into, but here are a few ideas to make the big data environment more secure during architecture and implementation phases:

1. Create data controls as close to the data as possible, since much of this data isn't "owned" by the security team. The risk of having big data traversing your network is that you have large amounts of confidential data—such as credit-card data, Social Security numbers, and personally identifiable information (PII)—residing in new places and being used in new ways. Also, you're usually not going to see terabytes of data siphoned from an organization, but you should be concerned about the search for patterns to find the content in these databases. Keep the security as close to the data as possible and don't rely on firewalls, IPS, DLP, or other systems to protect the data.
2. Verify that sensitive fields are indeed protected by using encryption so that when the data is analyzed, manipulated, or sent to other areas of the organization, you're limiting risk of exposure. All sensitive information needs to be encrypted once you have control over it.
3. After you've made the move to encrypt data, the next logical step is to concern yourself with key management. There are a few new ways to perform key management, including creating keys on an as-needed basis so you don't have to store them.
4. In Hadoop designs, review the Hadoop Distributed File System (HDFS) permissions of the cluster and verify that all access to HDFS is authenticated. When first implemented, Hadoop frameworks were notoriously bad at performing authentication of users and services. This allows users to impersonate as a user the cluster services themselves. You can be authenticated to the Hadoop framework using Kerberos, which can be used with HDFS access tokens to authenticate to the name node.

Challenge-Handshake Authentication Protocol (CHAP) is an authentication scheme used by Point-to-Point Protocol (PPP) hosts to authorize the identity of remote users and clients. CHAP occasionally validates the identity of the client by using a three-way handshake. This occurs simultaneously as the initial link is established, and can take place randomly at any time. Substantiation is based on a shared secret—for example, the user or client's password. Steps in the CHAP authentication scheme are as follows (reference Table 61.3):

1. Once the link has been established, the authenticator sends a "challenge" message to the peer.
2. The peer then responds with a determined value using a one-way hash function on the challenge and the secret combined.
3. The authenticator checks the response against the expected answer, or calculation of the expected hash value. If the values match, the authenticator acknowledges the authentication. If it does not match, the connection is terminated.

TABLE 61.3 Authentication Scheme used by CHAP Packets.

CHAP Packets						
Description	1 Byte	1 Byte	2 Bytes	1 Byte	Variable	Variable
Challenge	Code = 1	ID	Length	Response length	Challenge value	Name
Response	Code = 2	ID	Length	Response length	Response value	Name
Success	Code = 3	ID	Length		Message	
Failure	Code = 4	ID	Length		Message	

Randomly, the Authenticator Sends Another Challenge to the Peer and Repeats the Steps Mentioned Above

The ID chosen for the random challenge is also used in the corresponding response, success, and failure packets. A new challenge with a new ID must be different from the last challenge with another ID. If the success or failure is lost, the same response can be sent again and will trigger the same success or failure indication. For MD5 as hash, the response value is MD5(ID||secret||challenge), the MD5 for the concatenation of ID, secret, and challenge.

Wireless Security Access Controls

The IT Department has just been notified that the company wishes to allow personnel to access the company network from personal devices. A common approach to achieve this is to create separately named networks, (SSIDs), and corresponding VLANs inside your wired network. Segregating VLANs will separate the traffic between the other network traffic. Public wireless can be placed on a separate VLAN rather than private wireless, and there could also be a Mobile Wireless VLAN added to separate laptop wireless traffic from mobile devices.

However, you still want network access protection and a secure and simple way for key personnel to register their own devices for secure access to a private wireless network. Ask your wireless vendor if it sells a visitor management feature or a registration portal capable of walking personal devices through authorization and Wi-Fi provisioning. Another method for network access protection and wireless access control could be using a Mobile Device Manager (MDM) to drive these tasks.

WPA2-Personal requires every device to supply a Pre-Shared Key (PSK) derived from a passphrase. For example, devices on your trading floor might be required to supply the same random string of 20 characters known only to your IT department and configured during deployment. This method is often combined with MAC address filtering, so that only known devices with the right PSK are granted access. However, MAC address filters are easily bypassed, as are PSKs that are too short or too easy to guess. WPA2-Enterprise requires every device to complete an 802.1X log-on process that can support various authentication methods. For example, each device on your trading floor might be required to prove its identity with a unique digital certificate. Alternatively, each device might be required to supply a unique username and password configured during deployment and known only to your IT department. With this Wi-Fi access control method, you will be able to tell which individual machines are logged on. When used with certificates, WPA2-Enterprise is less vulnerable to password sharing and reuse, which are common problems when employees know a valid username/password or PSK and simply configure those into personal devices.

3. SUMMARY

Although only the most commonly used access mechanisms are discussed in this chapter, many extensions, combinations, and different mechanisms are possible. Trade-offs and limitations are involved with all mechanisms and access control designs, so it is the user's responsibility to determine the best-fit access control mechanisms that work for their business functions and requirements.

Also included in this chapter are the most commonly used access control policies. Since access control policies are targeted to specific access control requirements, unlike access control mechanisms, specific limitations cannot be inherently associated with them. And like access control mechanisms, it is up to the users to select the best policies for their needs. In addition to the limitations and issues, quality biometrics depends not only on the consideration of administration cost, but also on the flexibility of the mechanism helping the user in assessing or selecting among access control systems.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The dichotomy between types of companies and implementing layers of security led to the use of three types of access control mechanisms: denial of access control, mandatory access control, and role-based access control.
2. True or False? Discretionary access control (DAC), also known as file permissions, is the access control in Unix and Windows systems.
3. True or False? Mandatory access control (MAC) regulates user process access to resources based on an organizational security policy.
4. True or False? Role-based access control (RBAC) is a method whereby only authorized users can lose access to an environment and the sessions contained in the environment.
5. True or False? Role-based access controls tools are used for credentials, validation, authorization, and accountability in an infrastructure and the systems within.

Multiple Choice

1. What is a mechanical form and can be thought of as physical access to a room with a key?
   A. Qualitative analysis
   B. Vulnerabilities
   C. Spoofing
   D. Physical access control
   E. DHS
2. What might involve confirming the identity of a person or software program?
   A. Firewall
   B. Risk assessment
   C. Scale
   D. Authentication
   E. Bait
3. What is a secure method for authenticating a request for a service in a network?
   A. Organizations
   B. Fabric
   C. Kerberos
   D. Web application firewall
   E. Security
4. What requires every device to supply a Pre-Shared Key (PSK) derived from a passphrase?
   A. Cabinet-level state office
   B. Denial-of-service attack
   C. WPA2-Personal
   D. SAN protocol
   E. Taps
5. What is an authentication scheme used by Point-to-Point Protocol (PPP) hosts to authorize the identity of remote users and clients?
   A. Systems security plan
   B. Consumer privacy protection
   C. IP storage access
   D. Vulnerability
   E. Challenge-Handshake Authentication Protocol (CHAP)

Chapter 62

Assessments and Audits

Lauren Collins
kCura Corporation

1. ASSESSING VULNERABILITIES AND RISK: PENETRATION TESTING AND VULNERABILITY ASSESSMENTS

Penetration testing usually occurs in the compliance sphere, both in the semantics we use to describe technical points like "regulating deployments" and in the language technology vendors employ to describe those implementations. Compliance, however, is intolerant when it comes to accuracy in writing, and elusive inconsistencies in words can mean the difference between compliance and noncompliance. Erratic interpretations of conditions can lead to incongruous control selection, vague or unsuitable management responses, misrepresentation of controls to auditors, and many other problems. These differences can result in the very violations we are striving to avoid by integrating assessments prior to audits occurring. Penetration tests are valuable for multiple reasons:

- To identify vulnerabilities that may be evasive or impractical to detect with automated network or application vulnerability scanning software
- To identify high-risk vulnerabilities resulting from an amalgamation of lower risk vulnerabilities exploited in a noteworthy sequence
- To regulate the viability of a particular set of attack vectors
- To assess the magnitude of potential business and operational impacts of successful incidents
- To test the ability of network defenders to successfully detect and counter incidents

Multiple techniques can be used to conduct a penetration test; the variance is the volume of knowledge of the implementation factors pertaining to the system undergoing testing. Black box testing assumes no prior familiarity with the testing environment. A tester lays out the scenario and gathers information about the infrastructure prior to formulating an analysis. Black box testing can become exponentially expensive as time goes on. Not only is it labor intensive, but it is also taxing on the network and could cause noticeable slowness due to scanning. White box testing specifies all the information necessary: source code, IP addressing schemes, network diagrams, and any other pertinent information that is available. Believe it or not, gray box testing is also out there. Gray box testing depends on the type of test one can administer; which is entirely based on the extent of the information available.

Vulnerability assessments and penetration tests are habitually exercised interchangeably among technical associates, auditors, and controllers. The misconception is that a penetration test and a vulnerability assessment are notably different exercises. As a result, it is necessary for compliance professionals to become educated on the differences of each in an effort to ensure they are appropriately satiating compliance intentions that the controls perform in an approach they would expect and that they are correctly demonstrating controlled deployments to peers. At a high level, a vulnerability assessment is any interest aimed at research and subsequently at detailed prospective attack points (the vulnerabilities) within a given set of data. In a corporate information technology context, it usually embraces an attentive study of information systems (applications, systems, network devices, etc.) in order to identify concerns that compromise the security of that environment. Potential concerns may include omission of patching, unprotected configurations, and weak passwords.

Vulnerability assessments can be conventional, or they can focus on a more meticulous level of the technology stack, such as an application-level vulnerability assessment. Best practice is to incorporate practical scanning manners, such as running an automated vulnerability scan to query the scope of systems and devices. The next step would be to run a report on the security issues that might be present. The point of the action is to specify as many potential issues as possible that may negatively impact the environment's security. A vulnerability assessment will contain an automated scan of the environment using a proprietary scanning tool. Furthermore, both types of activities can include vulnerability scoring and

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00062-3

prioritization. In the case of a vulnerability assessment, the purpose is to provide information about the qualified severity level and remediation priority for the located issues. The penetration test, on the other hand, is designed to avoid providing attackers with information that gives them ideas on prolific attack opportunities.

From a regulatory compliance stance, the range of a vulnerability assessment or a penetration test will depend on the specific control objective you wish to meet. Since these conditions are sometimes used interchangeably, compliance specialists may find it necessary to ask some key questions rather than assume that a technical process or control implementation includes particular characteristics. Questions to ascertain if a vendor or partner is referring to vulnerability assessments or penetration testing include the following:

- Will the test include a vulnerability list, an activity report, or something else?
- What is the process output or report format?
- Will testers attempt to gain access to control sensitive resources?
- Is there a manual component, or is there just automated scanning?

By making invalid assumptions, you may not be receiving the controls and processes you hoped for. This could lead to more trouble than you had anticipated. Make sure you understand what the partners or vendors mean when they are discussing vulnerability assessments and penetration testing. Ask questions.

Port Scanning and Password Cracking

Port scanning is one of the most popular techniques a hacker can use to discover services that can be compromised. For instance, a port scanner will send a TCP SYN request to the host (or range of hosts) set to scan. Ping sweeps are also an option when attempting to define which hosts are available before starting the TCP port scans. Most port scanners only scan TCP ports by default, and some will have UDP by default as well. Some software packages will perform the discovery and auditing of your systems and network, or if you're really good and know your way around the command line on a switch, you can navigate around a network quickly to locate and there are free open-source programs as well. Network Mapper (NMAP), an open-source license, will allow scanning of UDP packets and is shown in Figure 62.1. Other common programs that can be used, other than NMAP, are SuperScan and NetScan. A scan will probe the accessible hosts for up to 65,535 viable TCP and UDP ports. You can select specific ports you'd like to scan in order to return fewer results, and also filter to view the services

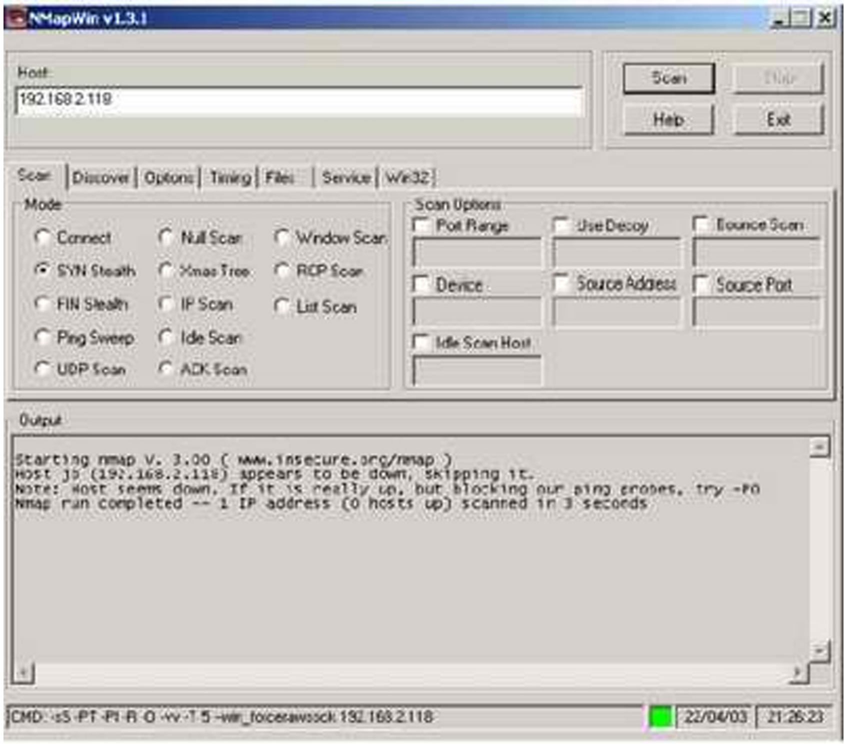

FIGURE 62.1 Network Mapper (NMAP), a utility used for scanning ports.

available. Port scans provide the following information from accessible hosts on the network:

- Network address of the hosts discovered
- Services and/or applications the hosts are running
- Hosts that are operational and reachable on the network

For your initial scan, it is recommended that you scan all ports from 1 to 65,535. There are many options to get as granular as you want. For instance, a scan can be performed on only well-known ports, or a scan may only involve a certain range of ports specific to your system. If the scanner is unable to find hosts that you are certain would show up, ICMP may be blocked. Once you have concluded what hosts are available and which ports are open, more sophisticate scans can be run to verify that the ports are open and that the tool is not reporting a false positive:

- *UDP Scan* is a basic UDP scan that looks for any open UDP ports on the host. This option is used to see what is running and determine whether or not Intrusion Detection Systems (IDS), firewalls, or other logging devices log the connection.
- *Connect* is a basic TCP scan that looks for any open TCP ports on the host. This scan is used to see what is running and determine whether or not IDS, firewalls, or other logging devices log the connection.
- *SYN Stealth* is a scan that initiates a half-open TCP connection, with the host potentially dodging IDS systems and logging. This option is a great scan for testing IDS systems, firewalls, and other logging devices.
- *FIN Stealth, Xmas Tree and Null* are scans that allow you to get creative by sending odd-shaped packets to the network hosts in order to see how the hosts respond. These scans basically alter the flags in the TCP headers of each packet, which allows you to test how each host handles them to point out weak TCP/IP implementations and patches that may need to be applied.

In Chapter 60, denial-of-service attack was one of the many attacks that were described. When running scans, it is possible to create your own denial-of-dervice attack and potentially crash applications or the entire network. Unfortunately, if there is a host on the network with a weak TCP/IP stack, there is no way to prevent your scan from becoming a DoS attack. To reduce the chance of this happening, use slow NMAP timing options when running scans. Refer to Figure 62.1 to see all the options available when running scans.

Password cracking is a process whereby a hacker or a system can retrieve passwords from records that have been stored or transmitted by a system. A popular tactic, and most common, is to try and guess the password. There is always the option to change the password and to state you have forgotten it; that approach works more than most would assume and has destroyed many people's virtual lives. In an organization, it is always more secure to assign a user a new password rather than allow them to answer a set of questions to recover their forgotten password. Although only administrators can assign new passwords, the extra security layer is a must. When reflecting how all of us have answered a series of questions to regain a forgotten password, consider a program running through a file system, file by file, attempting to obtain the record where the answers to your challenge questions and password are makes complete sense. That is exactly how a password can be cracked.

Encryption is a common process that individuals and organizations practice, and although it may take longer to crack, an encrypted password is easily attainable. If MD5 or SHA1 hash is used to encrypt a string of characters, that encrypted password is then a string of characters that is stored in the database. Rainbow tables of encrypted hashes contain all possible uses of a password, and such tools are available for free downloads. When comparing the rainbow tables and the target hashes, newer computers have a powerful enough processor and graphics card to achieve quantifiable results quickly. Graphic processing units (GPUs) were designed to do supercomputing where high-end math calculations can be done quickly in electronic trading and password cracking. GPUs are much faster than CPUs at calculating predefined tasks and comprise faster memory and wider input/output (I/O) channels to facilitate rapid computations.

There are several ways to limit the effectiveness of the powerful tools available to hackers. Salted hashes are a randomly generated piece of information that is added to the data prior to running it through the hashing process. A salt is arbitrarily generated information that is added to the data before running through the hashing process. Now the encrypted value cannot be cracked using rainbow tables, and the salt will have to be stored in encrypted databases utilizing a different salt for each password. A hacker would have to decrypt the database as well as each password and its record. Two-factor authentication is another technique organizations can use to intensify security measures. This is a form of security that will add greater security, even in the event a hashed password has been breached.

OVAL and CVE

Open Vulnerability and Assessment Language (OVAL) is the standard for determining vulnerability and configuration issues on systems. OVAL is an open community that was created by MITRE, and it is where knowledge can be shared and the content stored may be accessible to the public in an effort to standardize security efforts and how

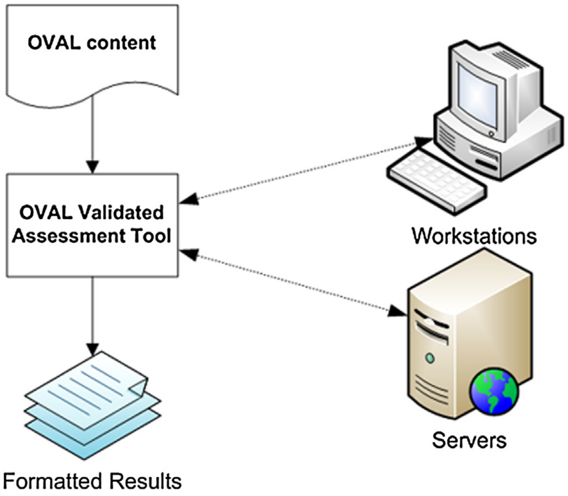

FIGURE 62.2 The assessment process of OVAL.

to assess and report systems and their states. OVAL utilizes a three-step system assessment:

1. Represent system information.
2. Articulate detailed machine states and report the results of the assessment.
3. Supply organizations with precise, stable, and actionable evidence to improve security.

Here is a case where OVAL could be useful: An organization designed their security procedures, protocols, and policies surrounding the Cisco products that were in their infrastructure. Three companies were acquired, and each of the three companies had hardware other than Cisco. Any vulnerability that was found prior to the acquisition and was corrected will no longer be valid once this other hardware is integrated into the infrastructure. Scanning your territory with three or four tools will now yield completely different results, making it more complex and prove that customized needs will have to be developed for the new assessment tool. Vendors, partners, and various other contributors will report the state of their systems, and this data should be referenced anytime your environment changes. The need for open standardization is clear in an example like this, and the process is represented in Figure 62.2.

Through public analysis, direct vendor support, and community contributions, OVAL provides vulnerability content that is reliable and verifiable. OVAL uses the robustness of XML to create a standard language for defining, assessing, and reporting vulnerabilities and configurations. Providing this vulnerability scanning content for the IT industry to collaborate and share technical details allows administrators and engineers to rapidly determine which systems are vulnerable and to rectify those vulnerabilities. And when there is a bug or a false positive, the community is astute to share fixes through use of publicly accessible repositories.

TABLE 62.1 Repositories Available Within OVAL.

Repository	Platform	Content
MITRE	Any platform	Open community based support for configuration and vulnerability information
Red Hat	Red Hat Enterprise Linux	Vulnerability content
NIST SCAP	Any platform	SCAP related

So, where do you go to get this content? There are tools that ship with vulnerability checks and receive regular content updates, or one of the OVAL repositories can assist. Table 62.1 represents the repository and its corresponding platform and content.

New repositories are added to OVAL's Web site after they have been created and verified. If you are assessing systems for use with the U.S. federal government, the NIST SCAP repository is your area of interest. Microsoft Security Guides, DISA Security Technical Implementation Guides, and Federal Desktop Core Configuration guides have been developed for assessing the systems established on current federal and vendor systems. Whether you are assessing the impact of the latest vulnerability or checking for federal compliance, the substantial public environment of OVAL developers and contributors will provide useful information to you and your infrastructure.

Common Vulnerabilities and Exposures (CVE) provides reference for information security vulnerability and exposures. MITRE assigns a CVE identifier to every vulnerability or exposure. A CVE is used to track vulnerability through different pieces of software, as a single CVE can affect multiple software packages and multiple vendors. The vulnerability is defined as a mistake in the software which may be directly oppressed by an attacker to compromise a system, and an exposure as a fault that could be used as an opportunity to launch an attack. CVE efforts include:

- Vulnerability Management
- Patch Management
- Vulnerability Alerting
- Intrusion Detection
- Security Content Automation Protocol (SCAP)
- National Vulnerability Database (NVD)
- US-CERT Bulletins
- CVE Numbering Authorities (CNAs)

When working with a common identifier, administrators and engineers find it less difficult to share data across separate databases, tools, and services. This data is not only easily accessible but can be integrated with ease. Unless a report comes up stating there is a bug, you're good to go. CVE is free and available for anyone who is interested in correlating data between diverse vulnerability or security tools, repositories, and services. Anyone could search or download CVE, copy it, redistribute it, reference it, and analyze it, provided you do not modify CVE itself. Companies are allowed to add links and pages to CVE's Web sites, products, publications, or other capacities. CVE Identifiers, or CVE names, are exclusive and collective identifiers for publicly known information. CVE-2001-0731 references a bug on how Google indexed a file without an external link. A CVE Identifier can be in the form of one of the following:

- Identifier number ("CVE-2001-0731")
- Description of the security vulnerability or exposure
- Any pertinent references (vulnerability reports and advisories or an OVAL-ID)

Using CVEs to identify vulnerabilities and exposures in your organization will allow for accurate and obtainable information from a vast selection of CVE information sources. CVE can help you make informed decisions and determine which of the capabilities are appropriate for your particular needs. Another plus is having the ability to create a suite of interoperable security tools and capabilities available as a translation mechanism.

2. RISK MANAGEMENT: QUANTITATIVE RISK MEASUREMENTS

By focusing on implementing best practices in your environment, you will be able to accomplish the following tasks:

- *Real-time alert configuration*: Data centers have become the core of a business, acting as an operations center. Managing logs is a significant step, and it is equally important to access and monitor alerts.
- *Proactive protection of the environment*: Log management tools and baseline analysis assist an organization to be proactive in their security methodology. Catching holes in security or issues existing, engineers can make a significant difference in time and money. Patching a server is an easy task, but when it is overlooked patch after patch, a vulnerability exists.
- *Incident containment*: When an unauthorized event occurs in an infrastructure, logs that are set up correctly can alert engineers and pinpoint the exact location quickly. If an engineer can see where the issue resides in a timely manner, that network or server can be isolated to prevent further damage.
- *Creation of an audit trail for forensics analysis*: When an intrusion is suspected or data loss has occurred, a rockstar audit trail will allow forensic data engineers to retrace the steps taken by someone who has entered the environment and correlate that data into usable information.
- *Creation of online documentation as the environment evolves*: IT must keep an activity log, tracking all logs across all the environments. Understanding the various systems and how they're performing allows engineers to shape the infrastructure as the business needs change.

Establishing a Baseline

Two types of alerts should be logged: faults that are generated by the system and the applications running on it, and faults or errors reported by the system's users. Fault logging and analysis is often the only way of finding out what is unsuitable about a system or application. The analysis of fault logs can be used to identify trends that may indicate deeper issues, such as defective hardware or a lack of competence or training for system administrators or users. All operating systems and many applications, such as database software, provide event logging and basic alerting faculties. This logging functionality should be configured to log all faults and send alerts if the error threshold is above an acceptable, defined threshold. Fault logging and analysis is often the only way to find out what is wrong with a system or an application. Documentation is key when defining which faults to record or report, who is responsible to investigate the faults, and an expected resolution time.

Since data center environments continue to grow, it has become more evident that administrators need to properly manage logs. Checking in on servers, firewalls, appliances, and switching gear event logs will assist IT to do more than simply check for reactive issues. If the process is managed and kept accurate, engineers can create a proactive environment that is capable of spotting and controlling issues before they even arise. Logs can also help an environment plan for the future. Network logs can show engineers where they are lacking and how they can competently plan for growth.

Auditing and Logging

Many devices that provide protection to the infrastructure within networks allow the ability to log events and take actions based on those events. This application system and monitoring provide details both on what has happened to the device and on what is happening in real time. It

provides security against lapses in perimeter and application defenses by alerting an administrator about issues, so that defensive measures can be enacted prior to any damage taking place. Without monitoring, an organization does not stand a chance of ascertaining whether a live application is under attack or if it has been compromised.

Business critical applications, processes handling valuable or sensitive information, previously compromised or abused systems, and those systems connected to third parties, all require active monitoring. Whenever suspicious behavior or critical events arise, an alert will be generated and must be acted on. Risk assessments must be done to determine logging levels and which actions are projected from a specified set of alerts. Logging and auditing work together, ensuring that users are only performing the activities they are authorized to perform. This data also plays a key role in preventing, spotting, tracking, and stopping unwanted or inappropriate activities. The levels of alerts, log reviews, and monitoring are an additional necessary component, and at least the following will need to be logged:

- Date, time, and other crucial events
- User ID or IP address
- Successful connections and failed attempts to access systems, data, or applications
- Files, servers, and networks accessed
- Changes to configurations
- Consumption of system utilities
- Exceptions and other security-related events, such as triggered alarms
- Activation of protection systems (intrusion detection systems and malware).

When these types of data are collected, that data will assist in access control monitoring and can provide audit trails when an incident is being investigated. Usually, logs are covered by some form of regulation of how many days it should be kept in case they are needed for an investigation. Employees need to be made aware of any firm monitoring policy activities on the network. Log files are a great source of information, but they serve absolutely no purpose if no one monitors them. When a firm purchases and deploys a solution, the product will not provide security unless the information is collected and analyzed on a regular basis. Some procedures require that the results be reviewed regularly to identify possible security threats and incidents. Each company differs in its processes based on the operations and content, and on how attractive that data may be.

Reviewing Policy Settings

Small networks can generate large amounts of information if the log settings are not optimal. Although log analyzers could automate the auditing and analysis of logs, storage for logs may be another challenge. This type of automated feedback frees up your resources, and your engineer can work to refine the log levels or parse through alerts of accurate threats. Recognizing true threats will help reduce the number of false positives. Eliminating false positives, while maintaining strict controls, is next to impossible. New threats and changes in the network infrastructure are ever changing and will likely affect the effectiveness of existing rule sets. Analyzing logs can provide a basis for focused security awareness training, reduced network misuse, and stronger policy enforcement.

Administrators have powerful access, and their activity should also be recorded and checked. A system restart may be prompted to correct serious errors, and those restarts may not be recorded if an administrator disables the alarm. Administrators' actions should be logged, notating start and finish times, who was involved and at what capacity, and what actions were taken. The name of the individual recording the information also should be recorded, along with the date and time. An organization with an internal audit team needs to maintain these records.

3. SUMMARY

An information security assessment and audit is the process of determining how effectively an entity being assessed (host, system, network, procedure, person—known as the assessment object) meets specific security objectives. Three types of assessment and audit methods can be used to accomplish this—testing, examination, and interviewing. *Testing* is the process of exercising one or more assessment and audit objects under specified conditions to compare actual and expected behaviors. *Examination* is the process of checking, inspecting, reviewing, observing, studying, or analyzing one or more assessment and audit objects to facilitate understanding, achieve clarification, or obtain evidence. *Interviewing* is the process of conducting discussions with individuals or groups within an organization to facilitate understanding, achieve clarification, or identify the location of evidence. Assessment and audit results are used to support the determination of security control effectiveness over time.

This chapter presents the basic technical aspects of conducting information security assessments and audits. It presents technical testing and examination methods and techniques that an organization might use as part of an assessment and audit, and it offers insights to assessors on their execution and the potential impact they may have on systems and networks. For an assessment and audit to be successful and have a positive impact on the security posture of a system (and ultimately the entire organization), elements beyond the execution of testing and

An Agenda for Action for Implementing Information Security Assessments and Audits

The processes and technical recommendations presented in this chapter enable organizations to (check all tasks completed):

_____**1.** Develop information security assessment and audit policy, methodology, and individual roles and responsibilities related to the technical aspects of assessment and audits.

_____**2.** Accurately plan for a technical information security assessment and audit by providing guidance on determining which systems to assess and the approach for assessment and audit, addressing logistical considerations, developing an assessment and audit plan, and ensuring legal and policy considerations are addressed.

_____**3.** Safely and effectively execute a technical information security assessment and audit using methods and techniques, and respond to any incidents that may occur during the assessment and audit.

_____**4.** Appropriately handle technical data (collection, storage, transmission, and destruction) throughout the assessment and audit process.

_____**5.** Conduct analysis and reporting to translate technical findings into risk mitigation actions that will improve the organization's security posture.

_____**6.** Establish an information security assessment and audit policy. This identifies the organization's requirements for executing assessments and audits, and provides accountability for the appropriate individuals to ensure assessments and audits are conducted in accordance with these requirements. Topics that an assessment and audit policy should address include the organizational requirements with which assessments and audits must comply; roles and responsibilities; adherence to an established assessment and audit methodology; assessment and audit frequency; and, documentation requirements.

_____**7.** Implement a repeatable and documented assessment and audit methodology. This provides consistency and structure to assessments and audits; expedites the transition of new assessment and audit staff; and addresses resource constraints associated with assessments and audits. Using such a methodology enables organizations to maximize the value of assessments and audits while minimizing possible risks introduced by certain technical assessment and audit techniques. These risks can range from not gathering sufficient information on the organization's security posture for fear of impacting system functionality to affecting the system or network availability by executing techniques without the proper safeguards in place. Processes that minimize risk caused by certain assessment and audit techniques include using skilled assessors and auditors, developing comprehensive assessment plans, logging assessor and auditor activities, performing testing off-hours, and conducting tests on duplicates of production systems (development systems). Organizations need to determine the level of risk they are willing to accept for each assessment and audit, and tailor their approaches accordingly.

_____**8.** Determine the objectives of each security assessment and audit, and tailor the approach accordingly. Security assessments and audits have specific objectives, acceptable levels of risk, and available resources. Because no individual technique provides a comprehensive picture of an organization's security when executed alone, organizations should use a combination of techniques. This also helps organizations to limit risk and resource usage.

_____**9.** Analyze findings, and develop risk mitigation techniques to address weaknesses. To ensure that security assessments and audits provide their ultimate value, organizations should conduct root cause analysis upon completion of an assessment and audits to enable the translation of findings into actionable mitigation techniques. These results may indicate that organizations should address not only technical weaknesses, but weaknesses in organizational processes and procedures as well.

examination must support the technical process. Suggestions for these activities (including a robust planning process, root cause analysis, and tailored reporting) are also presented in this chapter (see checklist: An Agenda for Action for Implementing Information Security Assessments and Audits).

The information presented in this chapter is intended to be used for a variety of assessment and audit purposes. For example, some assessments and audits focus on verifying that a particular security control (or controls) meets requirements, while others are intended to identify, validate, and assess a system's exploitable security weaknesses. Assessments and audits are also performed to increase an organization's ability to maintain a proactive computer network defense. Assessments and audits are not meant to take the place of implementing security controls and maintaining system security.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Penetration testing usually occurs in the compliance sphere, both in the semantics we use to describe technical points like "regulating deployments" and in the language technology vendors use to describe those implementations.
2. True or False? Port scanning is one of the most popular techniques a hacker can use to discover services that can be compromised.
3. True or False? Open Vulnerability and Assessment Language (OVAL) is not the standard for determining vulnerability and configuration issues on systems.
4. True or False? Two types of alerts should be logged: faults that are generated by the system and the applications running on it, and faults or errors reported by the system's users.
5. True or False? Since data center environments continue to grow, it has become more evident that administrators need to properly manage logs.

Multiple Choice

1. Many devices that provide protection to the infrastructure within networks, allow the ability to ______ events, and take actions based on those events.
   A. qualitative analysis
   B. vulnerabilities
   C. log
   D. physical access control
   E. DHS
2. Business critical applications, processes handling valuable or sensitive information, previously compromised or abused systems, and those systems connected to third parties, all require:
   A. firewall
   B. risk assessment
   C. scale
   D. authentication
   E. active monitoring
3. What are usually covered by some form of regulation of how many days they should be kept in case they are needed for an investigation?
   A. Organizations
   B. Fabric
   C. Kerberos
   D. Logs
   E. Security
4. What can generate large amounts of information if the log settings are not optimal?
   A. Cabinet-level state office
   B. Denial-of-service attack
   C. WPA2-Personal
   D. Small networks
   E. Taps
5. Who has powerful access, where their activity should be recorded and checked?
   A. Systems security plan
   B. Consumer privacy protection
   C. Administrators
   D. Vulnerability
   E. Challenge-Handshake Authentication Protocol (CHAP)

Chapter 63

Fundamentals of Cryptography

Scott R. Ellis, EnCE, RCA, RCIA
kCura Corporation

1. ASSURING PRIVACY WITH ENCRYPTION

Encryption provides a secure layer, at the storage byte level, under which information can be secured from prying eyes (see checklist: An Agenda for Action for Implementing Encryption and Other Information Security Functions). Data, or "plaintext" as it is called in cryptography, is rendered into cipher text through a ciphering process. Most importantly, encryption protects stored data. Files such as database data files, spreadsheets, documents, and reports can contain critical information—information which, if lost, could cause damage to:

- Sales generation
- Operations
- Reputation
- Competitive advantage
- Individuals
- Market capabilities
- Finances

Ultimately, the loss of enough data, especially were it due to incompetence, could be a business-ending event. Inadvertent disclosure of data, especially personally identifiable data, can mean financial liabilities and the need for restitution to injured parties.

Ensuring that files are encrypted in storage, everywhere, allows the files to be protected in the event of a breach of physical security. Should a hacker gain access to a system, database encryption will prevent her from accessing the database files. Whole-disk encryption will prevent her from accessing drive shares and pulling excel spreadsheets.

The past decade has seen additional liabilities and exposures of sensitive data in the form of lost backup tapes, lost laptops, and recycled computers that were not destroyed, encrypted, or wiped. After a third-party courier service lost a box of backup tapes, Bank of New York Mellon Corp. officials implemented a policy to encrypt data on all storage devices. Furthermore, they said they would limit the type and amount of confidential client data stored on tape backups. It took two losses of unencrypted data before the policy was launched.

Unfortunately, far too many companies wait for disaster to strike before they begin to think about all of the things they really need to do to ensure, or at least substantially mitigate, their risk of data loss. There are three primary reasons why industry executives are reticent to implement encryption:

1. The cost of doing it—the complexity of setting it up
2. Their feeling that it can't happen to them
3. The fear of data loss due to key loss—an inability to decrypt the data

The cost of implementing an encryption policy pales in comparison to the cost of a data loss due to a breach, or due to release of data simply because Joe Smith left his laptop on the train. In an interesting, real-life situation, the author of this chapter did, in fact, once find a small box of hard drives in a bag on a train. The drives were labeled backup01, backup02, and backup03. Fortunately, the box had a CDW Computer Centers, Inc. shipping label that identified a client number. After reaching out to a friend at the computer company on the label, who contacted the owner (a large university library), a reunion was arranged. The kindness and responsibility of strangers cannot serve, however, as a failsafe. If anything, the loss of ALL the backup data was narrowly averted. According to the library executive, the backup drives held *everything*. She also promised that the policy would be changing immediately.

Encryption also introduces an additional level of difficulty in the event of corruption. Certain segments of the drive, if they become corrupted, can make retrieval of the data more challenging. This necessitates

An Agenda for Action for Implementing Encryption and Other Information Security Functions

Encryption implementation recommendations presented in this chapter enable organizations to ask the following questions (check all tasks completed):

_____**1.** Does your product perform "cryptography," or otherwise contain any parts or components that are capable of performing any of the following "information security" functions?

_____**a.** encryption

_____**b.** decryption only (no encryption)

_____**c.** key management/public key infrastructure (PKI)

_____**d.** authentication (password protection, digital signatures)

_____**e.** copy protection

_____**f.** anti-virus protection

_____**g.** other (please explain): _________________

_____**h.** NONE/NOT APPLICABLE

_____**2.** For items with encryption, decryption, and/or key management functions (1.a, 1.b, 1.c above):

_____**a.** What symmetric algorithms and key lengths (56-bit DES, 112 / 168-bit Triple-DES, 128 / 256-bit AES/Rijndael) are implemented or supported?

_____**b.** What asymmetric algorithms and key lengths (512-bit RSA / Diffie-Hellman, 1024 / 2048-bit RSA/Diffie-Hellman) are implemented or supported?

_____**c.** What encryption protocols (SSL, SSH, IPSEC, or PKCS standards) are implemented or supported?

_____**d.** What type of data is encrypted?

_____**3.** For products that contain an "encryption component," can this encryption component be easily used by another product, or else accessed/re-transferred by the end user for cryptographic use?

the storage, offsite, of secure, unencrypted backups. This may seem contrary to the purpose of this chapter, but consider that:

a. The data must be delivered to the unencrypted DR site *encrypted*.
b. Access to the unencrypted backup site should be manned access only with biometric access controls and no Internet or network connectivity.
c. As physical security and controls *increase*, the need for encryption *decreases*.

Such a high level of security allows the data to be under a much higher degree of control than the data in production data centers. A regular program of data movement, refreshing, and redundancy checks should be in place to ensure against data corruption. Placing data on a disk is no guarantee that two years later (if the disk has sat idle) the data will be coherent. Data can become corrupt just sitting on a disk.

Organizations should consider and design a program that understands and includes recipient and sender environments, and ensures that data encryption and decryption are as seamless and unintrusive as possible. In Figure 63.1, a clock-face approach to security balances the need for physical security against the need for encryption. Observe how, as the network segment approaches the 12th hour, everything is encrypted.

This model only inserts five categories of devices and activities. Each "hour" could conceivably have its own protocols. The analogy of "hour" is used by this author simply to explain and set forth this model as one plausible way of making it easier to think about security, and thus categorize applications based on the activity or on the type of encryption required.

Physical Versus Logical Security

In this clock-face model, the level of physical security decreases the need for encryption security. Physical and data security are applicable to each of the items shown in this diagram. For some items, such as digital cameras, security can get complicated. GPS locators and remote wiping are available for many personal devices, but digital cameras, for example, do not have any sort of a mechanism for encrypting their memory cards.

Consider ranking things in order of "Needs no encryption" to "Must be encrypted." As mentioned previously, the security requirement for encryption decreases as physical security increases. For example, a computer, sealed in cement and sunk to the bottom of the Mariana trench needs not be encrypted. Cell phones and laptops, on the other hand, should be. Create a panel of advisors to assist with the ranking. Depending on the workplace and the industry, the threat level of various areas could vary. *Moving items from one position on the clock face to a lower number effectively diminishes the immediate need for encryption. This can be accomplished by increasing physical security.* For example, whether a PC in an office is more deserving of encryption than a data center that is hooked into the Internet and has lots of virtual traffic through it may be dependent on other factors. Increasing the security in the office may effectively reduce the need for encryption to a level beneath that of the data center.

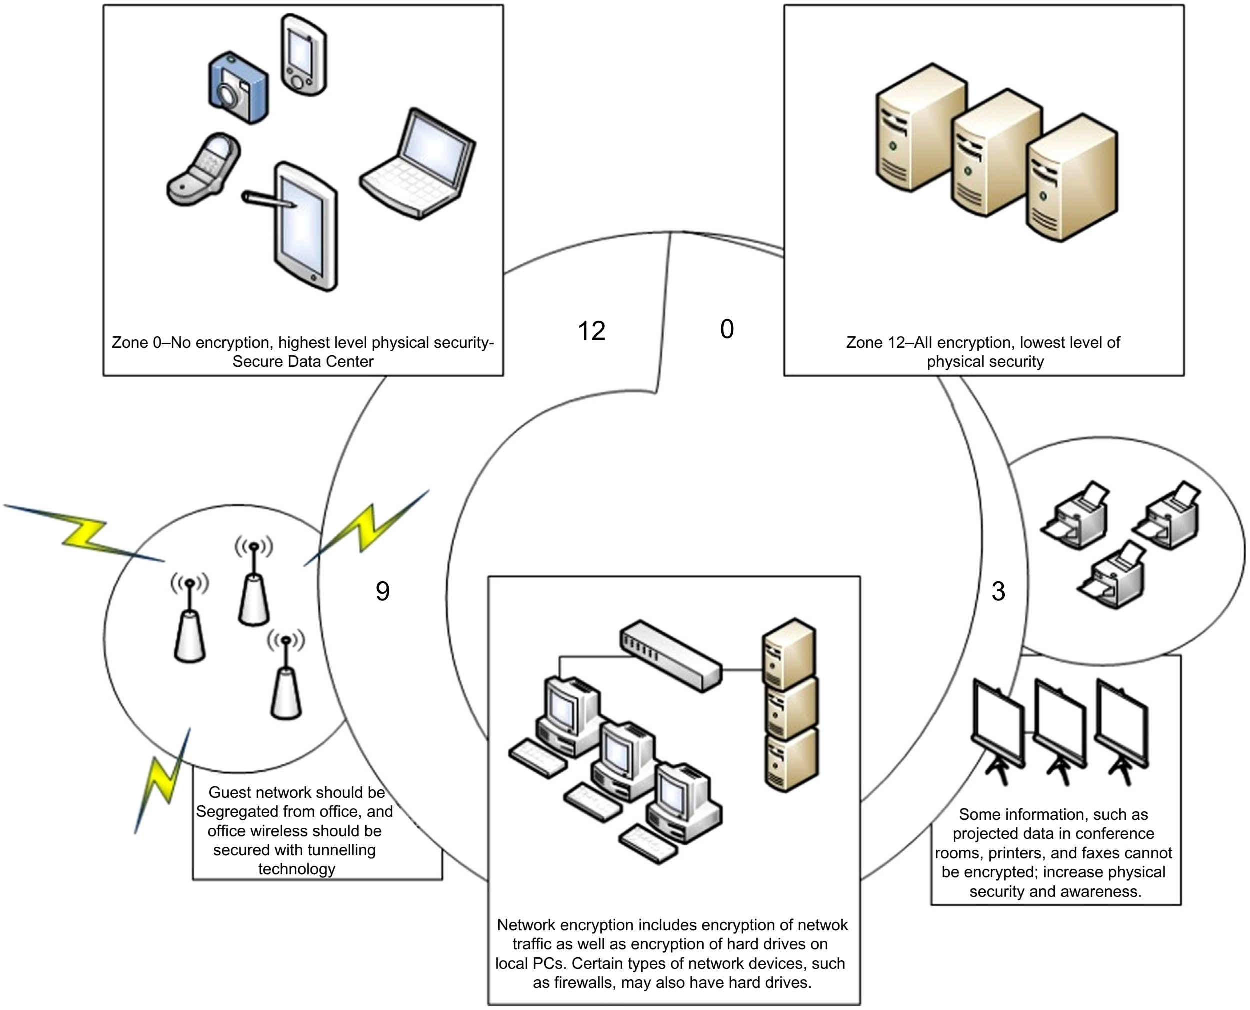

FIGURE 63.1 In a clock-face model, the most physically secure enterprise segments are at the zero hour, with the possibility of imminent attack or loss increasing up to the 12th hour. Note that the crescent line indicates increasing risk of loss, as well as a decrease in physical security.

Deciding which area is *more likely to be attacked first* requires some decision making—decisions that may, down the road, turn out to be wrong. Planning the implementation requires a *healthy* imagination, not a paranoid one. Too much paranoia can bog down the project, but a healthy dose of possible, real-life scenarios and a little imagination can make planning both enjoyable and effective. See the sidebar, Using Imagination to Effectively Plan, for an example scenario cooked up by the author with one of his coauthors.

As shown in Figure 63.1, devices can (generally) be ordered by Highest Concern for Encryption and least physical security to Least Concern for Encryption and highest physical security:

- Cell phones, PDAs, memory sticks, USB drives, tablets
- Data Center Web farm (financial data)
- Office PCs
- BackOffice Data Center
- Printers and Fax
- DR site (of course, in a failover, encryption protocols should be activated)
- Data Vault

Most organizations will need to take into account their own strategy. This allows for deployment of a planned implementation of encryption in an orderly and risk-biased way.

The Confidentiality, Integrity, and Availability (CIA) Model and Beyond

CIA, or confidentiality, integrity, and availability, is a model for establishing security and risk. It dovetails into the clock-face model presented herein in that CIA provides the litmus tests needed for assessing *into which* zone things must be placed.

Imagination Allows Accurate Ranking

One way of ranking is to imagine that a hacker is actually employed (unbeknownst to you) in your organization. One afternoon, after a particularly strange day of slowness in the network that you finally have been able to trace, you've narrowed it down to a group of three people: Justin Smirks, Nate Doomer, and Scotty Potomac.[1] You mention it to HR, who immediately panics, and later in the afternoon you learn (from an email) that Justin, Nate, and Scott were all fired, simultaneously, and they are really angry about it, and uttered some threats on their way out. "I'll get you, my pretty!" they hear Justin shouting as they drag Justin out kicking and screaming. Scott escapes security, grabs his backpack, crashes through the 23rd floor plate glass window with fist shaking in the air, and base jumps out to safety. Nate snarls, laughs, and vanishes in a puff of smoke, with an evil, lingering laugh, echoing through the corridors.

What are you going to do first (besides change your pants because you assume that Scott is "in" and did his damage on the way down, before his parachute finished opening)? In order of importance, would you say (very generally speaking) that it is more important to have disk encryption on the back-office systems or on the PCs? What is the highest priority?

It takes a special kind of mind to examine an organization and architect a solution that will decrease the vulnerable surface area of a system. Such a plan includes intrusion detection, prevention, firewall policy, and encryption, holistically. Unfortunately, the challenges of creating a comprehensive encryption strategy are daunting. To achieve affective encryption, it must be both seamless and the default action. There are three types of encryption that are well known:

1. Secret Key Cryptography (SKC): A single key decrypts and encrypts data.
2. Public Key Cryptography (PKC): A user's public key is used to encrypt data, and a private key is used to decrypt.
3. Hash Functions: A mathematical formula transforms the data to a set length of characters. For example, an MD5 hash reduces large blocks of information to a single, 128 bit, hexadecimal string.

Figure 63.2 demonstrates one example of how they are used and implemented in industry. Type 3 encryption is generally an augmentation of 1 and 2, used to send keys, to verify identity, and to ensure losslessness of information. By hashing a file before and after it is received, sender and recipient are then able to agree that they have the same file.

Users should be aware of the zones, what data lies within them, and the required encryption protocols. Auditors should check new processes, place them within the zones, and ensure compliance. If a new application happens to fail one of the tests, but passes another, move the application into a different zone until it can be made compliant. Zone 4 is "zone exceptions."

Step 1: Identify Areas of Risk:

1. The location of any personally identifiable information. This information takes priority.
2. Laptops, PDAs, any portable computers or systems, and remote workers that work with the data in item 1.
3. Email and other information transport communications.
4. Instant messages might be plaintext sent across the network and may be stored locally as well.
5. Vulnerable server drives and application communications.
6. Backups.

Step 2: Organize

Many organizations have very disparate legacy applications. Get organized—knowing the location, method of transport, and types of applications is critical. Understand where data is housed, how it gets transferred to other organizations, how employees generate and store data and where. Mapping out the ins and outs of how data gets generated and how it flows will both assist in understanding the overall security topology of the network and identify areas that should be encrypted. The end state may be that ALL information should be encrypted, and it may be that only some small amount of data should be encrypted. Ultimately, the following steps will assist in implementing and enterprise encryption strategy.

Step 3: Choose Cryptography Applications—Develop an Implementation Plan

All aspects of encryption that are planned for deployment should be fully understood. For example, using public key infrastructure (PKI) encryption gives users of the Internet the ability to exchange private data, securely, through the use of a public and private key pair that both recipient and sender share through a mutually agreed upon, trusted authority. Without this man-in-the middle trust factor, the process will not work. Essentially, the authority provides assignment and revocation of digital certificates that identify individuals and organizations. See the sidebar, How PKI Encryption Works, for more details on asymmetric key operations. The vendor selection team should have a great understanding.

Developing a strategy of encryption should be treated as a major project. From the outset, things like planning and compliance teams should be established. IT should be involved as well, and all access controls should be audited. Creating an encryption program makes sense, but only if the access controls system is tight. What good is an encrypted disk if the intruder can simply log in and see the unencrypted data right there? Additionally, the National Institute for Science and Technology (NIST) cryptographic toolkit provides standards and guidance over a wide range of the technology used in cryptography. Any vendors should be familiar with these standards and ensure compliance with them.

1. All persons listed in this sidebar are fictional. Any resemblance to any persons, living or dead, is purely noncoincidentally intentional.

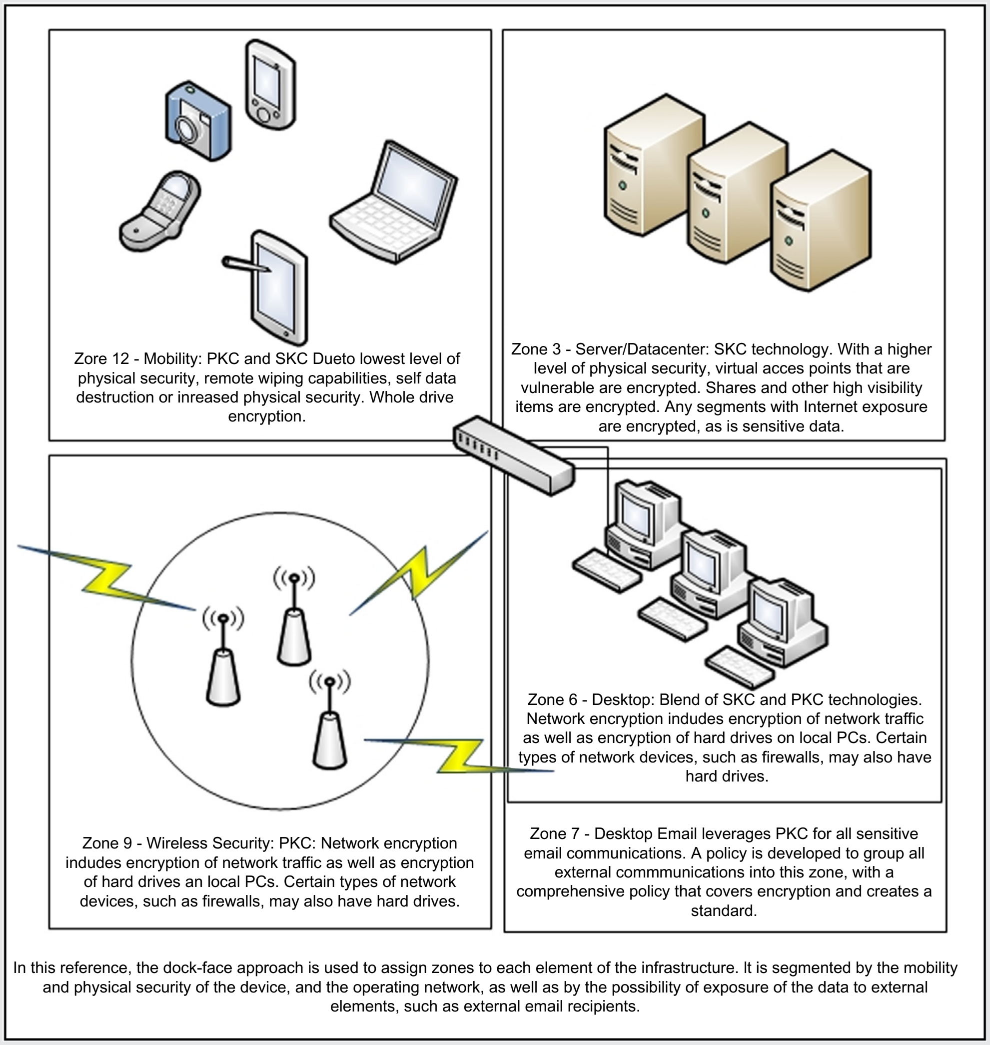

FIGURE 63.2 A sample of enterprise encryption. In this diagram, PKC and SKC forms of encryption are layered across the network in a zoned model of encryption.[2]

The final plan should be endorsed by management, and should be communicated to staff. It should include consequences for noncompliance. This plan should also mesh well with data destruction and retention policies.

Step 4: Implement Encryption Protocols

Sadly, no single "enterprise encryption" solution exists. Many vendors offer products A–Z that can be deployed and integrated together in a piecemeal solution, but this sort of hodgepodge approach can also be defined and planned by an experienced project manager. Such a plan will consider possible regulatory compliance requirements as well.

Step 5: Periodic Audits

Periodic audits will help ensure compliance. Conduct them as needed or as things change in significant ways. Maintenance of zone plans and software security measures should be frequent. All documentation should be kept up to date.

Confidentiality

To the degree that some information must be made available only to a certain group of people, this determines the level of restriction needed. Unauthorized access to information must be prevented. In areas of the network where information transmissions are uncontrolled and breach the perimeter, encryption of confidential data must occur.

This is especially true of wireless networks. Frequently, wireless networks are set up with weak, flawed, or no security.

2. The diagram in Figure 63.2 represents the author's viewpoint of how encryption *might* be deployed across a network that he just imagined in his head. The purpose of this is to create a model, a framework of sorts, that can be copied and adjusted as needed. It is meant to start a conversation, not end one.

How PKI Encryption Works

In this scenario of message encryption, as shown in Figure 63.3, the infrastructure relies on the use of a public key to encrypt any message sent. This is called public key cryptography. Traditionally, cryptography relies on a secret key used for both encryption and decryption. The most serious flaw of this method is that the secret key can be uncovered, discovered, or stolen.

A public key cryptography approach has a higher level of trust because, on the Internet, the transmission of a private key could be intercepted. So, the public key infrastructure is the preferred approach on the Internet. (The private key system is sometimes known as symmetric cryptography and the public key system as asymmetric cryptography.)

A public key infrastructure requires the following components:

- The certificate authority (CA) that performs the following functions:
  - Issues and verifies digital certificate that includes the public key
- A registration authority (RA):
  - Provides verification for the certificate authority
  - Issues the digital certificate to a requestor
- Storage directories to house the certificates and public keys.
- A system of certificate management.

In public key cryptography, when someone uses the service, a public and private key are simultaneously created using the same algorithm, such as the Rivest-Shamir-Adleman (RSA) algorithm. The certificate authority creates the key.

Subsequently, the private key is sent only to the requesting party. Then, the public key is made available in a common storage location as defined above. The private key remains private.

The private key is then used to decrypt information that has been encrypted by someone else using your public key. People using the public key system can find another user's public key in a central repository and use it to encrypt information that they are sending to them. Users then decrypt the message using their private key. In fact, a message encrypted using a public key can only be decrypted in this fashion.

A number of services, such as RSA, Verisign, and PGP, are all examples of companies in this vertical. Each of them provides PKI services.

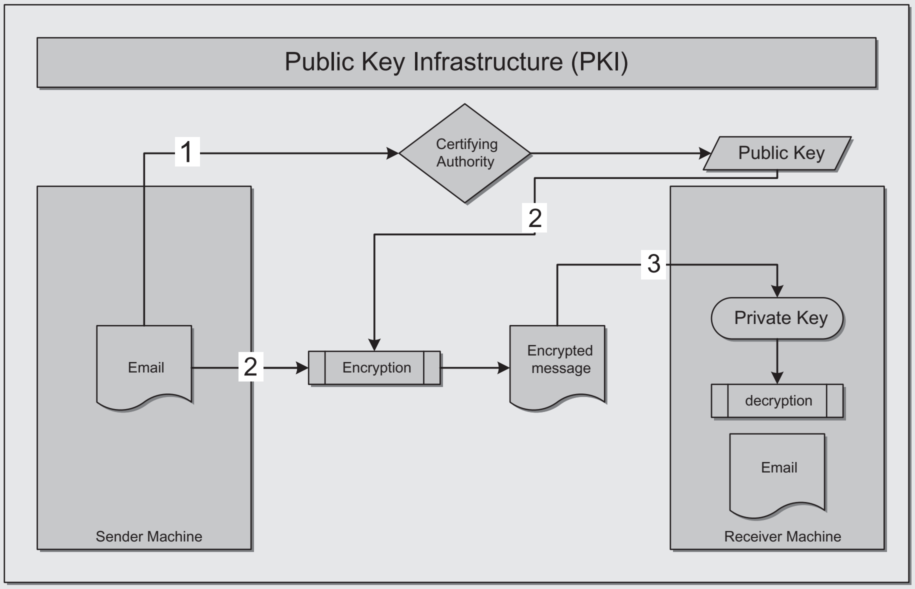

FIGURE 63.3 Step 1: The email requests the public key for the targeted recipient. Step 2: The email message is encrypted using the public key. Step 3: The email is unencrypted using the private key.

Integrity

Information should never be transmitted in ways that may disturb the integrity of the files or data. Unauthorized personnel should not be able to destroy or alter data. Hash values for files should be stored and transmitted with the file and accessed programmatically for validation.

Availability

Information that is so locked down that it is nearly inaccessible reduces the efficiency of operations. Information should be readily accessible to those who are authorized to view it.

Cryptographic Standards and Protocols: Block Ciphers—Approved Algorithms

Block ciphers utilize mathematical formulas that, when operated in cryptography, are called algorithms, and different flavors of algorithms are called ciphers. Block ciphers are a type of algorithm that converts plaintext into cypher text. They are called "block" ciphers because they work by enciphering a preset size of text at a time. Three well-known block ciphers are AES, Triple DES, and Skipjack.

AES

AES, published in FIPS 197 in February 2001, replaced DES. The government reviewed several different algorithms, but ultimately chose the Rijndael encryption algorithm to serve as a FIPS-approved symmetric encryption algorithm. The primary consideration here is that, by virtue of publishing under FIPS, the government created a standard whereby the U.S. government organizations (and others) may protect sensitive information.

Federal agencies also review the Office of Management and Budget (OMB) guidance, which suggests that AES is a standard that will be secure for 20 to 30 years. Furthermore, the OMB guidance warns agencies that the loss of cryptographic keys presents a risk to the availability of information needed to accomplish critical mission tasks and objectives.[3]

In today's world of extremely complex communication systems, the need for a full understanding of security, which includes a detailed understanding of the business itself first, has never been more apparent. The ability to protect and secure information depends entirely on the ability of those doing the protecting to understand the business. It cannot be solely dependent on the mathematical strengths of the encryption algorithm or the ability of someone to classify certain information. Likewise, you cannot count on the classification of the material to always be an accurate predictor of which encryption algorithm to use. Flexibility MUST be built into the system. There MUST be a way for the governing organization to stop, look, and listen. Many factors must be considered in choosing an algorithm and process for encryption, and these factors may, of course, change over time. An inflexible policy risks failure. The following factors are most relevant:

- How well the implementation of the algorithm will perform in specific software, firmware, or hardware configurations;
- The ability to develop a functional key management system, or of the algorithm to mesh with an existing solution;
- The fragility of the of the information to be protected; and/or
- Any requirements to interoperate, globally, where encryption algorithm restrictions may exist.

Considered in total, these requirements demand the implementation of a flexible implementation and policy that mixes the best of breed software with best practices derived from the individual business requirements.[4]

3. http://csrc.nist.gov/drivers/documents/ombencryption-guidance.pdf.

4. Additional information regarding the use of AES can be found in CNSS Policy No. 15, Fact Sheet No. 1 National Policy on the Use of the AES to Protect National Security Systems and National Security Information, June 2003.

2. SUMMARY

Ultimately, the best encryption protocol would be completely seamless, effective, and transparent. A seamless encryption utility would provide, across the enterprise, a single-console approach to management. Phones, PDAs, hard drives, servers, network communications, and the like, all could be added to the encryption layer with the drag of a mouse. An effective algorithm is one that is not just unbreakable in the near foreseeable future, but rather, is simply unbreakable. A transparent system would provide encryption services without any observation by the user. They would not know, nor would they have reason to know, that their emails are encrypted using PKC technology. Unfortunately, modern information technology has not been able to provide any sort of all-encompassing program for managing secure communications. In the meantime, it is up to information technologists to cobble together a best of breed solution that protects and secures information simultaneously.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Encryption provides an insecure layer, at the storage byte level, under which information can be secured from prying eyes.
2. True or False? Ultimately, the gain of enough data, especially were it due to incompetence, could be a business-ending event.

3. True or False? Ensuring that files are encrypted in storage everywhere allows the files to be protected in the event of a breach of physical security.
4. True or False? The cost of implementing an encryption policy pales in comparison to the cost of a data loss due to a breach or to release of data simply because Joe Smith left his laptop on the train. In an interesting, real-life situation, the author of this chapter did, in fact, once find a small box of hard drives in a bag on a train.
5. True or False? Encryption also introduces additional levels of difficulty in the event of corruption.

Multiple Choice

1. The data must be delivered to the following unencrypted DR site:
   - **A.** Qualitative analysis
   - **B.** Vulnerabilities
   - **C.** Log
   - **D.** Encrypted
   - **E.** DHS
2. Which unencrypted backup site should be manned accessed with only biometric access controls and no Internet or network connectivity?
   - **A.** Firewall
   - **B.** Risk assessment
   - **C.** Scale
   - **D.** Access
   - **E.** Active monitoring
3. As physical security and controls *increase*, the need for encryption does which one of the following:
   - **A.** Organizations
   - **B.** Fabric
   - **C.** Decreases
   - **D.** Logs
   - **E.** Security
4. Who or what should consider and design a program that understands and includes recipient and sender environments, and ensures that data encryption and decryption are as seamless and unintrusive as possible?
   - **A.** Organizations
   - **B.** Denial-of-service attack
   - **C.** WPA2-Personal
   - **D.** Small networks
   - **E.** Taps
5. Deciding which area is *more likely to be attacked first* requires some __________decisions that may, down the road, turn out to be wrong.
   - **A.** Systems security plan
   - **B.** Consumer privacy protection
   - **C.** Administrators
   - **D.** Decision making
   - **E.** Challenge-Handshake Authentication Protocol (CHAP)

Chapter 64

Security Through Diversity

Kevin Noble
Verizon Terremark

The Internet and all the interconnected nodes reflect an aggregate of disparate technology, a new spectrum of human interaction, and the most competitive domain for nation states, industry and enterprise. The Internet is the mirror reflecting all things important or not. Revolutions are sparked, small grievances cascade into protest, aspects of wars are wages in the digital medium that is the Internet. Experimentally, the Internet is proving to be one of the most interesting medium to threaten with tangible and results beginning to be recognized as indistinguishable from any other threat. The interconnected scale assures threat can succeed with a high probability of success and yet avoiding attribution. Characteristics of success digital threats are creative with magnitude impact and requiring victims to adapt and pay attention. Most Internet related threats are opportunistic such as malware designed to steal access to bank accounts and computer virus infections primarily concerned with the theft of information. Yet none of these threat come close to the most successful attacks are excessive in magnitude of impact that cause economies to fail or governments to initiate a response other then to suppress social media.

Ubiquity and compatibility are driving forces of the computer revolution driving down cost while the application of ‘security through diversity’ is still emerging as a strategic decision. In most case geography and distribution of content achieve diversity. For the largest sites providing search capabilities, banking, social media, connective computing becomes critical and relevant as the scale and risk increases, protecting any single host with the application of diversity typically fails. Internet services provided through distribution and replication achieve geographical diversity and perhaps some security, intended or otherwise. Distribution and replication is resistant to denial of service and is an ideal response to cataclysmic events. Immense cataclysmic events require strategic contingency planning by nation states. In general, a decimated region such as the earthquake that hit Haiti in January 2010 required a rebuild of a telecommunications infrastructure. Mobile communication towers were deployed allowing mobile phones to communicate voice and SMS messages fairly quickly. As with many disasters, the distribution and volume of devices supported quickly provided a means to support the emergency needs and can be viewed as a principal of ‘security through diversity’ might be viewed as an aspect of ‘ resilience’. Emergency management can shorten the duration of recover and intercede in cascading events and coordinate efforts.

An example of an unnatural threat that probably caused permanent physical damage and destruction would be the stuxnet worm in June of 2010. The stuxnet worm may exemplify threats to come as it targeted programmable logic controllers for a specific set number of centrifuges. Generally, centrifuges operate at high speed at a steady pace. The stuxnet worm disrupted and delayed the uranium enrichment process by changing centrifuge speeds in such a way as to damage the equipment while falsely reporting nominal speeds through the programmable logic controllers. The stuxnet worm had a direct impact on an Iranian program that according to public information, delayed and disrupted the program successfully. The most successful targeted threats will achieve permanent physical damage and disruption.

To be successful, stuxnet had to contain enough exploits to vulnerabilities to ensure spreading and infecting enough host to achieve success. A defender that threat models may impose policies to forbid sharing of USB devices or an aggressive patch cycle. Direct Internet access was not a factor in the successful exploit of the device, many organization incorrectly consider devices and nodes safe based on “direct Internet access.”

By volume, Internet related attacks that seek targets of opportunity for financial gain and financial loss can be insured to a point. Also significant in volume are ‘targeted threats’ where after an intrusion, sensitive data is targeted as part of a larger espionage effort. Information security practitioners focused on espionage related intrusions joke ponders “how many of the fortune 500 companies have been exploited?’ the answer given is ‘500’”.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00064-7

Not a pervasive today but in 2001-2005 worms were effective and opportunistic. Aggressive targeted attacks are rare but tend to exceed in magnitude of other threats and usually have an effective duration to achieve specific goals such as denial of service (long duration) or the exfiltration of information (usually short). Exfiltration as an act itself usually only takes the time to find the location and compress and send the data out.

Specific DDoS attacks require enough magnitude and duration to achieve goals set by the attacker(s). In general DDoS must exceed the targets ability to resist for the intended duration or achieve short-term goals such as extortion. Response to DDoS threats generally require a balance of efforts to assure legitimate traffic remains while selectively banishing malicious traffic that can be dynamic, excessive, and requires logically adjusting content delivery, avoiding single point failures in location, services, and peering. The diversification in points of presence, scalable services, and working with service provides has proven successful.

Diversity as an aspect of resilience and part of a larger information security (see checklist: "An Agenda For Action For Implementing Information Technology Security") effort is costly and difficult. Decisions to hosting divergent technologies that provide the same service redundantly might keep you operational, but it comes with a necessary investment in effort and skill. Intentionally going against top trends appears to be happening naturally as technology refreshes and proliferates. Implementing diversity as doctrine may not be necessary, diversity of product selection has introduced risk to individuals while proliferation may protect all devices as a larger digital biosphere. For technology, mass manufacturing and commoditized hardware reduces cost, competition naturally introduces diversity. Software for the most part seeks to ensure uniformity across platforms and hardware, diversity in delivery comes at a price.

The most common diversity strategy is in use today by most large-scale businesses that choose to store data far enough away from the original site as to be unaffected by natural disasters and phenomena such as power outages. But is this enough? Natural disasters cover only one threat vector to sustainability and operational readiness. The information age must balance uniformity and ubiquity in the face of threats though adaptation and vigilances.

1. UBIQUITY

Most modern attacks take advantage of the fact that the majority of personal computers on the Internet are quite nearly in the same state. The way an attack works against a single host works identically on millions. At the global scale of interconnected systems, diversity is the best response to threats against ubiquity; it is the closest to a digital autoimmune system possible with the inclusion of patch remediation and defense in depth. Patch remediation only safeguards against known threats and assumes emerging threats pose little risk, the risk is worth absorbing or at least tolerated. Defense in depth as a strategy is requires threat modeling that includes methods to detect and suppress attacks. Business continuity planning rarely includes cyber threats or considers intrusions that can impact the core business.

At the smallest level of individual hosts, delayed patching of applications or with the operating system itself can be viewed as the single cell micro organism prone to automated compromise. Home users pay little attention to software updates unless prompted by self-updating software. Users rely on notification and antivirus software to protect and inoculation against common threats to the Internet as a whole more then providing individual protection. The modicum of protection from automatic updates and an antivirus solution is sufficient to individuals. Working with this knowledge, an attacker will seek to automate attacks by taking advantage of the ubiquity of systems, targets of opportunity. Consider the nation state threat, utilizing an exploit that works against a majority of home systems. The investment in

An Agenda for Action for Implementing Information Technology Security

The purpose of the checklist is a high level guide to assess the overall security and privacy status associated with a contracted IT service or outsourced business processing. The objective of checklist is to assist program managers, security officers, system owners and contracting officer representatives to identify areas of increased security risk and areas not in compliance with national and agency policy and standards. The key areas examined in this checklist include (Check All Tasks Completed):

_____**1.** IT, Physical and Personnel Security Policy

_____**2.** Organization/Contract General Provisions

_____**3.** System, Data and Device Inventory

_____**4.** System Certification and Accreditation

_____**5.** Contingency Planning

_____**6.** Continuous Monitoring/Risk Management

_____**7.** Weakness Management

_____**8.** Incident Handling and Response

_____**9.** Security Configuration Management

_____**10.** Security Training

developing an exploit provide a nation state with capability to disable and disrupt.

You don't have to be a nation state with an agenda to develop an offensive cyber capability. Imagine for a moment that you're an attacker or small collective of attackers. In general, the consideration is opportunistic and the effort is to develop exploits that within the collective skill set of the group, select popular operating systems with the most common software packages, and select the most ideal target within that subset. An economist might see the concept as a "probability density function," or what is simply referred to as "getting the most bang for the buck." Targets of opportunity are proportional to the ubiquity of the vulnerability itself. It is certain that as a given computer system moves away from the densest pool of common systems, an attacker needs to work harder to accommodate the difference, which thus can reduce the likelihood of compromise.

Ubiquity at scale introduces complexity in engineering updates, distribution considerations and that act as a safeguard. Large scale solutions leads to a natural diverse properties. Still, engineering to requirements with anticipated tolerances might still be the best approach for any design. "All security involves trade-offs."[1] To that end diversity is not a security strategy in itself but is an aspect of defense in depth, part of a holistic approach to security and possibly an insurance policy against unenforceable odds.

2. EXAMPLE ATTACKS AGAINST UNIFORMITY

Ubiquitous systems are good, cheap, replaceable, and reliable—until mass failure occurs. It certainly pays to know that ubiquity and uniformity are the absolute right choices in the absence of threats. That is not the world we occupy, even if not acknowledged. What would it take to survive an attack that had the potential to effectively disrupt a business or even destroy it?

If you operate in a service industry that is Internet based, this question is perhaps what keeps you up at night—an attack against all your systems and services, from which you might not recover. Denial of Service (DoS) is a simple and straightforward attack that involves an attacker making enough requests to saturate your network or service to the point at which legitimate business and communications fails. The distributed denial-of-service (DDoS) attack is the same type of attack against a uniform presence in the Internet space but with many attacking hosts operating in unison against a site or service.

1. Bruce Schneier, *Beyond Fear,* Springer-Verlag, 2003.

Businesses with real bricks-and-mortar locations in addition to selling goods and services over the Internet can survive a sustainable DDoS attack against the Internet-based business because the bricks-and-mortar transactions can carry the company's survival. Inversely, businesses with the ubiquitous use of credit cards that require the merchant authorization process can suffer when the point-of-sale system can't process credit cards. That business will simply and routinely have to turn away customers who can only pay by credit card. Yet a business with both a strong Internet and a solid bricks-and-mortar presence can survive an outage through diversity.

For years DDoS was used as a form of extortion. Internet-based gambling businesses were frequent targets of this type of attack and frequently made payouts to criminal attackers. It is common for Internet-based businesses to utilize DDoS mitigation services to absorb or offload the undesired traffic. The various means that an attacker can use in combination to conduct DDoS have escalated into a shifting asymmetrical warfare, with each side adapting to new techniques deployed by the other side.

Companies have failed to counter the straightforward attack and have gone out of business or ceased operations. A company called Blue Security Inc. that specialized in combating unsolicited email messages (spam) by automating a reply message to the senders had its subscribers attacked. Blue Security's anti-spam model failed in 2006 when spammers attacked its very customers, causing the company to shut down the service in the interest of protecting the customers.[2]

Successfully mitigating and combating an attack is achieved by either having enough resources to absorb the attack or offloading the attack at some point prior to reaching a site or service. The DDoS attack is partially successful where the target is uniformly presented and responsive and does not react fast enough to the attacks. A common means to protect against DDoS or Internet-based outages is to have a diverse business model that does not rely only on the Internet as a means to conduct business. Diverse business models may hold considerable cost and bring in differential revenue, but they ensure that one model may in fact support the other through sustained attacks, disasters, or even tough times. Employing the concept of security through diversity gives decision makers more immediate options.

Though the DDoS attack represents the most simplistic and basic attack against an Internet-based institution, it does require an attacker to use enough resources against a given target to achieve bottlenecking or saturation. This represents the immediate and intentional attack, with one

2. "Blue Security, spam victim or just a really bad idea," *InfoWorld/Tech Watch* article, May 19, 2006.

or more attackers making a concentrated effort against a target.

3. ATTACKING UBIQUITY WITH ANTIVIRUS TOOLS

Attackers use obfuscation, encryption, and compression to install malicious code such as viruses, worms, and Trojans. These techniques are tactical responses to bypass common antivirus solutions deployed by just about everyone. The number of permutations possible on a single executable file while retaining functionality is on the order of tens of thousands, and these changes create just enough diversity in each iteration to achieve a successful infection. An attacker needs to mutate an executable only enough to bypass detection from signature-based antivirus tools, the most common antivirus solutions deployed.[3]

It is possible for anyone to test a given piece of malicious code against a litany of antivirus solutions. It is common practice for attackers and defenders both to submit code to sites such as www.virustotal.com for inspection and detection against 26 or more common antivirus solutions. Attackers use the information to verify whether a specific antivirus product will fail to detect code while defenders inspect suspected binaries.

At the root of the problem is the signature-based method used to inspect malicious code. Not all antivirus solutions use signature-based detection exclusively, but in essence, it is the fast, cheap, and, until recently, most effective method. If malware sample A looks like signature X, it is most likely X. A harder and less reliable way to detect malicious code is through a technique known as *heuristics.* Each antivirus will perform heuristics in a different manner, but it makes a guess or best-effort determination and will classify samples ranging from safe to highly suspect. Some antivirus solutions may declare a sample malicious, increasing the chances of finding a false positive.

Another factor in analysis is entropy, or how random the code looks upon inspection. Here again you can have false positives when following the trend to pack, distort, encrypt, and otherwise obfuscate malicious code. The measurement of entropy is a good key indicator that something has attempted to hide itself from inspection. Keep in mind that because commercial software uses these techniques as well, you have a chance of false positives.

At the 2008 annual DEFCON conference in Las Vegas, a new challenge was presented: Teams were provided with existing malicious code and modified the code without changing functionality, to bypass all the antivirus solutions. The team that could best defeat detection won. The contest was called "race to zero." The organizers hoped to raise awareness about the decreased reliability on signature-based antivirus engines. It is very important to say again that the code is essentially the same except that it can avoid detection (or immediate detection).

Given that it is possible and relatively easy for attackers to modify existing malicious code enough to bypass all signature-based solutions yet retain functionality, it can be considered a threat against any enterprise that has a ubiquitous antivirus solution deployment. Infections are possible and likely and increasing; the risk is not a doomed enterprise, but usually information disclosure could lead to other things.

Those who choose Apple's OS X over PC operating systems enjoy what might be coined in some circles as immunity or resistance in the arena of malicious code. An attacker would have to invest time and effort into attack strategies against the Apple platform over and above the efforts of attacking Windows, for example. Without getting caught up in market share percentages, Apple is not as attractive for attackers (at the time of this writing) from the operating system perspective.

One might think the application of diversity can be applied simply by hosting differential operating systems. This is true but rarely works if derived from a strict security perspective. It could be beneficial to switch entirely to a less attacked platform or host a differential operating system in a single environment. On the sliding scales of diversity and complexity, you might have immune hosts to one attack type against a given operating system. This also means that internal information technology and support teams would have to maintain support skills that can support each different platform hosted. Usually business decisions make better drivers for using and supporting diverse operating systems than a strategy of diversity alone. In my observations, routine support will be applied where individuals have stronger skills and abilities while other platforms are neglected.

4. THE THREAT OF WORMS

In 2003 and 2004, the fast-spreading worm's probability represented the bigger threat for the Internet community at large because patching was not as commonplace and interconnectivity was largely ignored compared to today. A number of self-replicating viruses propagating to new hosts autonomously are known as *worms.* A worm-infected host would seek to send the worm to other hosts, using methods that would allow for extremely aggressive and rapid spread. Infected hosts did not experience much in the way of damage or intentional data loss but simply were not able to communicate with other hosts on heavily infected networks. Essentially, the worms became an

3. G. Ollmann, "X-morphic exploitation," IBM Global Technology Services, May 2007.

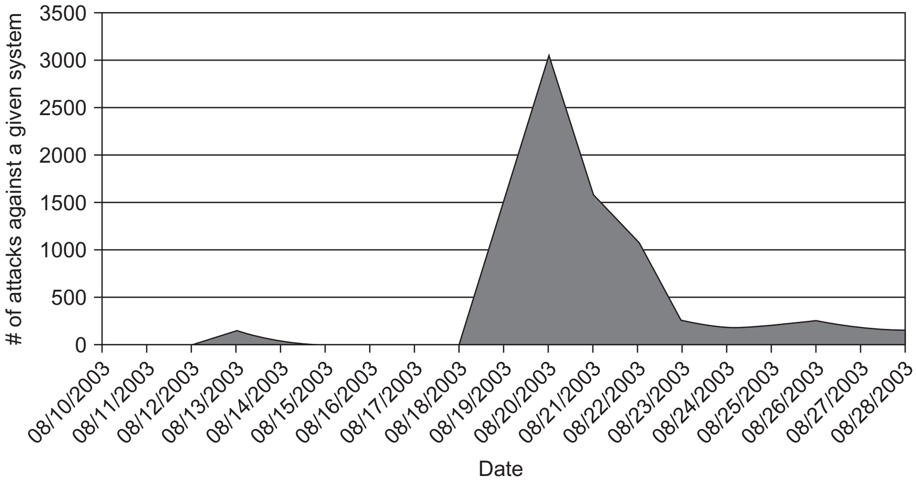

FIGURE 64.1 Tracking infected hosts as part of the Nachi outbreak.

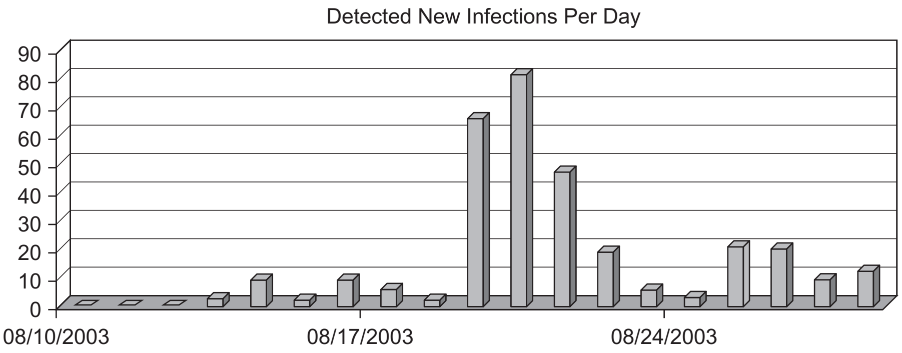

FIGURE 64.2 Nachi finding new hosts to infect.

uncontrolled DDoS tool, causing outages and performance issues in networks in which the worm gained enough hosts to saturate the networks by seeking yet more hosts.

While responding to the outbreaks of both the Nachi and MSBlas worms in 2003 for a large business, there was enough statistical information about both worms from the various logs, host-based protection, and packet captures to reconstruct the infection process (see Figure 64.1). The Nachi worm in particular appeared to have an optimized IP address-generating algorithm allowing nodes closer on the network to become infected faster. When you consider that the worm could only infect Windows-based systems against the total variety of hosts, you end up with a maximum threshold of targets. The network-accessible Windows hosts at the time of the worm attack were about 79.8% of the total network; other platforms and systems were based on Unix, printers, and routers. Certainly some of the hosts were patched against this particular vulnerability. Microsoft had released a patch prior to the outbreak. But at the time of the Nachi worm outbreak, patching was deployed at set intervals in excess of 60 days, and the particular vulnerability exploited by Nachi was not patched. The theoretical estimated number of systems that could succumb to infection was right at the total number of Windows systems on the network—just under 80%, as shown in Figure 64.2—meaning that the network was fairly uniform.[4]

Given this scenario, it would stand to reason that the infection would achieve 100% and only depend on each newly infected system coming up with the appropriate IP address to infect new hosts. Yet the data reveals that the total infection was only 36% of the total Windows systems and took 17 days to really become effective, as shown in Figure 64.3. It seemed that enough vulnerable Windows hosts had to be infected to seed the next wave of infected hosts.

The worm's pseudorandom IP address selection was a factor in the success of its spread; you had to have a vulnerable system online with a specific IP that was targeted at that time. Once enough seed systems became infected, even a poor pseudorandom IP generator would have been successful in allowing the worm to spread at speeds similar to a chemical chain reaction. Systems would become infected within seconds rather than minutes or hours of connecting to a network. Over the years the probability of

4. K. Noble, "Profile of an intrusion." research paper, Aug. 2003.

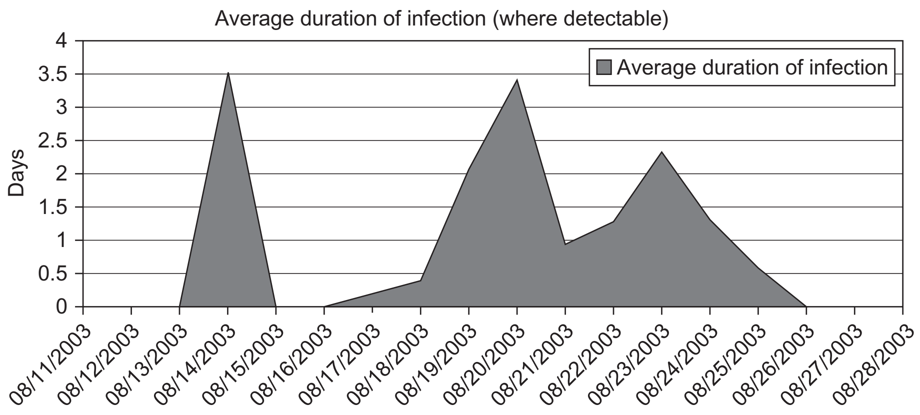

FIGURE 64.3 The Nachiworm requires continual infection to achieve network saturation.

a mass windows infection was reduced considerably by addressing vulnerabilities. Microsoft immunity response to reduce vulnerabilities is addressed by the 'Secure Development Lifecycle', a process that has proven effective to worm behavior of exploiting vulnerabilities automatically. It has been argues that massive worm outbreaks have declined because of the diverse number of systems has increased, the cost to develop an effective exploit has increased to a point where it would not be used carelessly, and DDoS can provide control while a worm may not.

Other factors for a successful defense against the worm included a deployment of host-based firewalls that blocked port traffic. The Nachi worm traffic was mostly from non-local untrusted networks making port filtering an easy block for the attack. Other factors that reduced the spread included the fact that a number of systems, such as mobile laptop computers, did not remain connected after business hours (users taking the laptops home, for example). Emergency patching and efforts to contain the spread by various groups was also a big factor in reducing the number of vulnerable systems. The Nachi worm itself also prevented infection to some systems by simply generating too much traffic, causing a DoS within the network. Network engineers immediately began blocking traffic as generated by the Nachi worm and blocking entire subnets altogether. The speed of the infection caused a dramatic increase in traffic on infected networks and induced a reaction by many network engineers looking for the root cause and attacking the problem by blocking specific traffic.

Additional resistance to infection from the Nachi worm in this case was achieved through unintended diversity in time, location, and events surrounding the vulnerable systems. Perhaps we can call this being lucky; vulnerable hosts were protected by not being connected or not needing to connect during the potential infection window. The last interesting thing about worms that achieved mass infection during 2003 is that those worms still generate traffic on the Internet today—perhaps an indication of a sustained infection, re-infection, or intentional attacks.

Though unintentional diversity and rapid response to the outbreak were success factors, an emerging response to automated attacks was intrusion detection systems (IDSs) being deployed in greater numbers. Though prevention is ideal, detection is the absolute first and necessary step in the process of defense. A natural transition to automating defense was the mass implementation of intrusion protection systems (IPSs), which detect and block based on predefined understandings of past attacks and in some cases block based on attack behavior.

Making a choice to be diverse as a means to improve security alone might not be beneficial. If you choose two different backup methodologies or split offices between two different operating systems just for the sake of security and not business as the driver, then cost in theory nearly doubles without gaining much. Ideally diversity is coupled with other concepts, such as security.

5. AUTOMATED NETWORK DEFENSE

Computer systems that transact information at great speed have similar properties to chemical reactions, once started, quite difficult or impossible to stop. The defense of the network can't happen at real time where humans alone provide security. Alternate, machines may not make the best decision about traffic and thresholds. A balanced approached that blends human decision with machine response is ideal. Network security defense from the perspective of the security provides is to leverage automation simply because it is cheap, trying to keep out most of the bad things while allowing everything else to traverse without interference, reflecting customer demand.

If a security service provider took time to inspect every anomaly to the point where overall traffic performance were degraded, it would be advantageous for an attacker to exploit the heavy inspection process to create

a performance issue up to the point of denying service. This very consideration causes both the default policies on IPS and IPS customers to acquiesce and to allow a percentage of bad traffic as a trade for performance or connectivity in general.

At first you might be surprised at the position taken by IPS vendors and customers. Denying all anomalous and malicious traffic might be the sales pitch from IPS vendors, but the dichotomy of having a device designed for automated protection being used for automated DoS by an attacker against the very business it was suppose to protect would scare off anyone. IDS as an industry does nothing more than strike a balance between common attack prevention while allowing everything else—perhaps a worthy goal on some fronts.

6. DIVERSITY AND THE BROWSER

An evolutionary adaptation to security has driven attackers to exploit the Web browser. Because everyone has one, the Web browser represents the most promising avenue to information exploitation. Straightforward attacks involving simply spraying an attack across the Internet are not how one exploits browsers. Attacks usually take advantage of vulnerabilities only after a browser retrieves code from a malicious Web site. The remote attack is not a sustainable attack. Most popular browsers that host the means for automatic patching allow the browsers to be secured against known vulnerabilities. Still, not everyone takes advantage of new browser releases that include patches for remote exploits and serious issues. Attacking the user behind the browser along with attacking the browser seems to be a winning combination yielding a higher percentage of compromised hosts for attackers.

Conceptually, could the browser be the weapon of choice that collapses an entire enterprise? It is possible but highly unlikely. The two most common browsers are Microsoft's Internet Explorer and Mozilla's Firefox, making them the most targeted. Most browsers are not monolithic; adding code to view pages and perform animation are common practices. Browser extensibility allows anyone to integrate software components. Serious vulnerabilities and poor implementation in some of these extensions has led to exploitable code but usually demands a visit from a vulnerable browser. Since many of us don't use the same software package added to our browsers, this sort of threat, though risky to any enterprise from the standpoint of information disclosure, does not represent the sort of survivability issues security diversity seeks to remedy.

The application of diversity to browsers could be remedied by the selection of an uncommon browser or by choosing extensibility options offered by vendors other than the most common ones. The tradeoff is gaining a host of compatibility issues for the ability to thwart browser-specific attacks.

Operating systems (OSs) are the Holy Grail of attacked platforms simply because OS has all the control. Most attacks in some form or fashion seek to gain partial authority within the OS or to dominate and persist within the OS altogether. Rootkits seek to hide the behavior of code and allow code (usually malicious) to operate with impunity on a given system. Even when the browser or other services are attacked, it would probably be more advantageous for the attacker to seek a way into the OS without detection. Targeted threats are customized to evade detection and to leverage vulnerabilities discovered over time to infiltrate, these threats are difficult to detect and diversity at any layer is but an obstacle. Being a target means you have a specific value, either monetary or in information. Many fortune 500 companies have been targeted for trade secrets, industrial espionage, pending patents and were victimized and lost data, credibility and information but few went out of business as a result of an intrusion or series of intrusion. These types of threats do not appear to have a short term affect on the institutions except in the case where the company H.B. Gary was targeted and had nearly all the internal emails of the organization released publically. As a security firm, H.B. Gary lost considerable business unlike the institutions H.B. Gary sought to assist.

Opportunistic threats from generic malware and phishing affect individuals and the accounts and information they posses. Many individuals utilize a single account and password or a very short list of account and password pairs. Once accounts and passwords are exposed, attackers automate the use of those accounts against banking sites, social networking sites, and others. A unique and diverse set of accounts and password that are well protected offer the best defense against wholesale identity theft.

It is fairly safe to say that all systems host vulnerabilities, some are difficult to uncover and establishing a defense against future unknown vulnerabilities makes sense. Many well-developed operating systems can randomize memory layouts and as a means to reduce the predictability specific offsets for code execution. Attackers craft exploits to take advantage of vulnerabilities found in code and in some cases, well crafted exploits allow remote command execution. The Windows OS, with the lion's share of systems, is the ubiquitous platform of choice for attackers. Microsoft has made considerable efforts in the past few years to combat the threats and has introduced technologies such as stack cookies, safe handler and chain validation, heap protection, data execution prevention (DEP), and address space layout randomization (ASLR). Each is designed to thwart or deter automated attacks and protect code execution

from exploitation through any vulnerability. ASLR can be defeated and many examples exist in the public, but ASLR affords protection at scale from generic automated attacks and the diversity of memory layouts from host with the same vulnerability are afforded protection.

Of each of these low-level defenses implemented in code today, ASLR seeks to increase security through diversity in the Vista OS. Theoretically, on a given system on which an attack is possible, it will not be possible again on another system or even the same system after a layout change that occurs after a reboot. Certainly altering the behavior between systems reduces risk.

The current implementation of ASLR on Vista requires complete randomized process address spacing to offer complete security from the next wave of attacks.[5] Certainly the balance of security falters and favors the attacker when promiscuous code meets any static state or even limited entropy of sorts.

7. SANDBOXING AND VIRTUALIZATION

The technique of *sandboxing* is sometimes used to contain code or fault isolation. Java, Flash, and other languages rely heavily on containing code as a security measure. Though sandboxing can be effective, it has the same issues as anything else that is ubiquitous—one flaw that can be exploited for a single sandbox can be exploited for all sandboxes.

Expanding the concept in a different way is the virtual hosting of many systems on a single system through the use of a *hypervisor.* Each instance of an OS connects to the physical host through the hypervisor, which acts as the hardware gateway and as a kernel of sorts. Frequently the concept of virtualization is coupled to security as the layer of abstraction and offers quite a bit of protection between environments in the absence of vulnerabilities.

The concept of virtualization has considerable long-term benefits by offering diversity within a single host but requires the same diligence as any physical system compounded by the number of virtual systems hosted. It is fair to say that each host that contains vulnerabilities may therefore put other hosts or the entire core of the hosting physical system at risk. The risk is no different than an entire room full of interconnected systems that have emergent properties. Frequently, security professionals and attackers alike use virtualization as a platform for testing code and the ability to suspend and record activity, similar to a VCR.

5. M. Dowd and A. Sotirov, 2008 Black Hat paper, "Bypassing browser memory protections," Black Hat USA 2008 Briefings and Training, Caesars Palace, Las Vegas August 2-7, 2008 [https://www.blackhat.com/presentations/bh-usa-08/Sotirov_Dowd/bh08-sotirov-dowd.pdf]

In many cases, the push to virtualized system or service is a business decision with operational cost being a key driver. Systems that share resources can leverage unused resources. However, with increased frequency, security is considered a benefit of virtualization. This is true only in the context of virtual environments achieving isolation between guests or host and guest. This is a clear goal of all the hypervisors on the market, from the VMware product line to Windows Virtualization products.

For quite some time it was possible for security researchers to work with malicious samples in a virtualized state. This allowed researchers to essentially use the context of a computer running on a computer with features similar to a digital video recorder, where time (for the malicious sample) can be recorded and played back at a speed of their choosing. That was true until the advent of malicious code with the ability to test whether it was hosted in a virtualized environment or not. Recent research has shown that it is possible for malicious code to escape the context of the virtual world and attack the host system or at least glean information from it.

Two competing factors nullify using virtualized environments as a means of archiving simple security through diversity. It will continue to be possible to detect hosting in a virtual environment, and it is possible to find the means to exploit virtual environments, even if the difficulty increases. However, this just means that you can't rely on the hypervisor alone. Vulnerabilities are at the heart of all software, and the evolutionary state of attacking the virtualized environments and the hypervisor will continue to progress.

The decline of virtualized environments as a security tool was natural as so many in the security field became dependent on hypervisors. In response, the security field will essentially adapt new features and functions to offset vulnerabilities and detect attacks. Examples include improved forensics and hosting virtualized environments in ways to avoid detection.

In nature, colorful insects represent a warning to others of toxicity or poison if eaten. Similarly, some in the security field have taken to setting virtualization flags on real, physical machines simply to foil malicious code. The more hostile malicious code will shut itself down and delete itself when it determines it is in a virtual host, thus preventing some infections.

8. DNS EXAMPLE OF DIVERSITY THROUGH SECURITY

It is fair to say that the Internet requires a means to resolve IP addresses to names and names back to IP addresses. The resolving capabilities are solved by

Domain Name Server with a well-defined explanation on how any DNS is supposed to function being published and publicly available. In most cases you may choose to use a provider's implementation of DNS as a resolver or deploy your own to manage internal names and perform a lookup from other domains.

If prior to 2008 you had selected the less popular DJBDNS[6] over the more popular BIND, you would have been inoculated (for the most part[7]) against the DNS cache-poisoning attack made famous by Dan Kaminski. Depending on your understanding of the attack against what you are trying to protect, theoretically all information transacted over the Internet was at the complete mercy of an attacker. Nothing could be trusted. This is actually not the limit of the capabilities, but it is the most fundamental. The threat to survivability was real and caused many to consider secure DNS alternatives after the attack was made public.

Rapid and automated response is the most common defense technique. Making the decision to act late is still beneficial but risky because the number of attackers capable of performing the attack increases with time. Reaction is both a good procedural defense and offers immunity and lessons learned. As part of the reaction, you could assume that the DNS is not trusted and continue to operate with the idea that some information not be from the intended sources. You could also make a decision to disconnect from the Internet until the threat is mitigated to a satisfactory level. Neither would seem reasonable, but it is important to know what threat would constitute such a reaction.

9. RECOVERY FROM DISASTER IS SURVIVAL

Disaster recovery is often thought of as being able to recover from partial data loss or complete data loss by restoring data from tape. With the considerably lower cost of dense media, it is now possible to continuously stream a copy of the data and recover at any point in time rather than the scheduled time associated with evening backup events. In many cases the backup procedure is tested frequently, whereas the recovery procedure is not.

Unfortunately, many assume that simply having backups means that recovery is inevitable or a foregone conclusion. For others, the risk associated with recovery has led to many organizations never testing the backups for fear of disruption or failure. Perhaps in the interest of diversity from the norm it is beneficial to frequently and procedurally test restore operations. Though security diversity is a survival technique, recovery is the paramount survival tool in everyone's arsenal.

When does diversity work against you? It might not be possible to quantify the advantage of selecting diversity over ubiquity other than the cost in procurement, training, and interoperability. It is quite possible that an investment in "bucking the system" and using uncommon systems and services won't just cause issues; it would drive your competitive advantage into oblivion. This is the single biggest reason to avoid security through diversity, and it will be pointed out repeatedly. Security through diversity starts early and is embraced as a matter of survival. Military and financial institutions abide by the diversity principals in investments and decision-making. Though a threat is not always understood, the institutionalizing lessons learned tend to live on, forcing change and adaptation that require diversity as a fundamental principal of survival.

10. SUMMARY

In the digital domain, Geo-dispersal or resources and disaster recovery concepts seems the ideal area in which to institute a separate and diverse architecture from that of a production environment. Segregation of resources and environments offers a tangible boundary that may increase resilience to threats. Software updates, early threat detection and suppression is but only part of a solution. As Dan Geer indicated in his essay on the evolution of security,[8] we already have an evolutionary approach to systems by centralizing enterprises into safe, climate-controlled environments. We protect systems with IDS all while making copies of critical data and systems, just in case. Making changes to systems as we acquire them is rarely undertaken to the level necessary to ensure survival; most systems have very few changes from the "out-of-box" state or factory default because we fear that the changes will make the system unstable or ineffective.

"Diversity ad absurdum" is cost prohibitive and not ill advised. Making a leap to complete diversity will inevitably fail for businesses and institutions. Competition in products and solutions is naturally coupled to diversity in much the same way as DNA differs in iterations of generations. At some point, security through diversity is an action to be considered through threat modeling, where it can be applied on as many fronts as possible and at the lowest levels as feasible. At the higher levels, consideration for a process to apply hygiene to processes, code snippets, and each protocol adds cost but acts to protect. A changed state might be more desirable then the original

6. D. J. Bernstein, author and developer of DJBDNS.

7. Though DNS queries might be verified where DJBDNS was deployed, the upstream DNS server could still be vulnerable, making it important to know from where you get your DNS names.

8. D. Geer, "The evolution of security," *ACM Queue,* April 2007.

state as an assurance against 'native attack code'. Forced change adds complexity and resilience at a cost yet might be required where untrusted computing takes place.

In selecting diversity and all the investment and issues that go along with it, an instant beneficial byproduct is a rich set of choices in many areas, not just security. Decision makers have options not available to monoculture networks and systems. For example, if you have deployed in production at least two different manufacturers, routers or firewalls, you will have people trained specifically for each or both. Instead of a competitive nature of driving out competition, you have the ability to match the appropriate models to various parts of a given network and not depend on the product catalog of a single vendor. In the immediate situation of threats to an entire product line, a diverse decision process such as exchanging routers is available. Someone with a single affected vendor has a limited choice bracket of solutions. Additionally, anyone trained or certified in more than one company's equipment portfolio can more easily adapt to any additional needs increasing choices and options.

Of all the security diversity solutions available, perhaps having a skilled and adaptable workforce trained in all the fundamental aspects of computer security offers the best solution. The simplistic statement of "the best defense is a good offense" in this case, means that security professionals should be able to defend from attacks, understand attacks, and be prepared to perform the forensic analysis and reverse-engineering needed to understand attacks. Adaptation and resiliency are key traits to diversity.

Security through diversity starts early and is embraced as a matter of survival. Military and financial institutions abide by the diversity principals in investments and decision-making. Though a threat is not always understood, the lessons learned during an attack tend to live on, forcing change and adaptation that require diversity as a fundamental principal of survival of a diverse skill set during a given threat to survival makes all the difference in the world.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Ubiquity and compatibility are driving forces of the computer revolution driving down cost while the application of 'security through diversity' is not emerging as a strategic decision.
2. True or False? By volume, Internet related attacks that seek targets of opportunity for financial gain and financial loss, cannot be insured to a point.
3. True or False? Specific DDoS attacks require enough magnitude and duration to achieve goals set by the attacker(s).
4. True or False? The most common diversity strategy is in use today by most large-scale businesses that choose to store data far enough away from the original site as to be affected by natural disasters and phenomena such as power outages.
5. True or False? Most modern attacks take advantage of the fact that the majority of personal computers on the Internet are quite nearly in the same state.

Multiple Choice

1. What systems are good, cheap, replaceable, and reliable—until mass failure occurs?
   A. Ubiquitous
   B. Vulnerabilities
   C. Log
   D. Encrypted
   E. DHS
2. Who use obfuscation, encryption, and compression to install malicious code such as viruses, worms, and Trojans?
   A. Attackers
   B. Risk assessment
   C. Scale
   D. Access
   E. Active monitoring
3. A number of self-replicating viruses propagating to new hosts autonomously are known as:
   A. Organizations
   B. Fabric
   C. Worms
   D. Logs
   E. Security
4. Other factors for a successful defense against the worm included a deployment of host-based firewalls that blocked:
   A. Organizations
   B. Denial of service attack
   C. WPA2-Personal
   D. Port traffic
   E. Taps
5. If a security service provider took time to inspect every anomaly to the point where overall traffic performance were degraded, it would be advantageous for an attacker to exploit the heavy inspection process to create a performance issue up to the point of:
   A. Systems security plan
   B. Consumer privacy protection

C. Denying service
D. Decision making
E. Challenge-Handshake Authentication Protocol (CHAP)

EXERCISE

Problem

The most common diversity strategy is in use today by most large-scale businesses that choose to store data far enough away from the original site as to be unaffected by natural disasters and phenomena such as power outages. But is this enough?

Hands-On Projects

Project

Ubiquitous systems are good, cheap, replaceable, and reliable—until mass failure occurs. It certainly pays to know that ubiquity and uniformity are the absolute right choices in the absence of threats. That is not the world we occupy, even if not acknowledged. What would it take to survive an attack that had the potential to effectively disrupt a business or even destroy it?

Case Projects

Problem

Conceptually, could the browser be the weapon of choice that collapses an entire enterprise?

Optional Team Case Project

Problem

When does diversity work against you?

Chapter 65

Online e-Reputation Management Services

Jean-Marc Seigneur
University of Geneva

1. INTRODUCTION

During the past three decades, the computing environment has changed from centralized stationary computers to distributed and mobile computing. This evolution has profound implications for the security models, policies and mechanisms needed to protect users' information and resources in an increasingly globally interconnected open computing infrastructure. In centralized stationary computer systems, security is typically based on the authenticated identity of other parties. Strong authentication mechanisms, such as Public Key Infrastructures (PKIs) [1,2], have allowed this model to be extended to distributed systems within a single administrative domain or within a few closely collaborating domains. However, small mobile devices are increasingly being equipped with wireless network capabilities that allow ubiquitous access to corporate resources and allow users with similar devices to collaborate while on the move. Traditional, identity-based security mechanism cannot authorize an operation without authenticating the claiming entity. This means that no interaction can take place unless both parties are known to each others' authentication framework. Spontaneous interactions would therefore require that a single, or a few trusted Certificate Authorities (CAs) emerge, which, based on the inability of a PKI to emerge over the past decade, seems highly unlikely in the foreseeable future. In the current environment, a user who wishes to partake in spontaneous collaboration with another party has the choice between enabling security and thereby disabling spontaneous collaboration or disabling security and thereby enabling spontaneous collaboration.

The state-of-the-art is clearly unsatisfactory, instead, mobile users and devices need the ability to autonomously authenticate and authorize other parties that they encounter on their way, without relying on a common authentication infrastructure. The user's mobility implies that resources left in the home environment must be accessed via interconnected third-parties. When the user moves to a foreign place for the first time, it is highly probable that the third-parties of this place are a priori unknown, strangers. However, to interact with these strangers is still necessary, for example, to access his/her remote home environment. It is a reality that users can move to potentially harmful places, for example, by lack of information or due to uncertainty, there is a probability that previously unknown computing third-parties used to provide mobile computing in foreign places are malicious. The assumption of a known and closed computing environment held for fixed, centralized and distributed computers until the advent of the Internet and more recently mobile computing. Legacy security models and mechanisms rely on the assumption of closed computing environments, where it is possible to identify and fortify a security perimeter, which protects against potentially malicious entities. However, in these models, there is no room for anytime anywhere mobility. Moreover, it is supposed that inside the security perimeter, there is a common security infrastructure, a common security policy or a common jurisdiction where the notion of identity is globally meaningful. It does not work in the absence of this assumption.

A fundamental requirement for Internet and mobile computing environments is to allow for potential interaction and collaboration with unknown entities. Due to the potentially large number of previously unknown entities and simple economic reasons, it makes no sense to assume the presence of a human administrator who configures and maintains the security framework for all users in the Internet, for example, in an online auction situation, or even in proximity, for example, when a user moves in a city from home to workplace. This means that either the individuals or their computing devices must decide about each of these potential interactions themselves. It applies to security decisions too, for example,

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00065-9

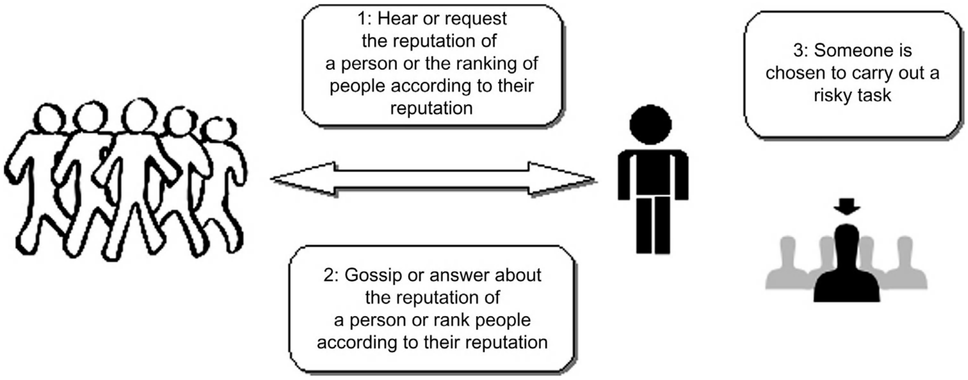

FIGURE 65.1 High-level reputation primitives.

concerning the enrollment of a large number of unknown entities. There is an inherent element of risk whenever a computing entity ventures into collaboration with a previously unknown party. One way to manage that risk is to develop models, policies and mechanisms that allow the local entity to assess the risk of the proposed collaboration and to explicitly reason about the trustworthiness of the other party in order to determine if the other party is trustworthy enough to mitigate the risk of collaboration. Formation of trust may be based on previous experience, recommendations from reachable peers or the perceived reputation of the other party. Reputation, for example, could be obtained through a reputation system such as the one used on eBay [3]. This chapter focuses on this new approach to computer security, namely, reputation management. Nowadays almost all communication and marketing agencies have online reputation monitoring and analysis as part of the services they propose to their customers. Although these services are the most well-known, this chapter covers all the types of services that compose a complete reputation management solution stack.

The next section of this chapter discusses the general understanding of the human notion of reputation. Section 3 explains how this concept of reputation fits into computer security. The fourth section presents the state of the art of attack-resistant reputation computation. Section 5 gives an overview of the current market of online reputation and e-reputation services. We conclude by underlining the need to standardize online reputation for increased adoption and robustness.

2. THE HUMAN NOTION OF REPUTATION

Reputation is an old human notion: the Romans named it "reputatio": "reputatio est vulgaris opinio ubi non est veritas." [4]. Reputation may be considered as a social control mechanism [5], where it is better to tell the truth than to have the reputation to be a liar. That social control mechanism may have been challenged in the past by the fact that people could change of region to clear their reputation. However, as we move toward an information society world, changing of region should have less and less impact in this regard because reputation information is no more bound to a specific location, which is also a good news for reputable people who have to move to other regions for other reasons, such as a job relocation. For example, someone might want to know the reputation of a person that she or he does not know, especially when this person is considered to be chosen to carry out a risky task among a set of potential new collaborators. Another case may be that the reputation of a person is simply gossiped. The reputation information may be based on real, biased or faked facts, for example, faked by a malicious recommender who wants to harm the target person or biased by a recommender who is a close friend of the person to be recommended. The above Latin quote translates to "reputation is a vulgar opinion where there is no truth" [4]. The target of the reputation may also be an organization, a product, a brand, a location... The source of the reputation information may not be very clear, for example, it may come from gossips or rumors whose source is not exactly known or it may come from a known group of people. When the source is known, the term recommendation can be used. Reputation is different than a recommendation who is made by a known specific entity. The following Figure 65.1 gives an overview of the reputation primitives.

As La Rochefoucauld wrote[1] a long time ago, recommending is also a trusting behavior. It has not only an impact on the recommender's overall trustworthiness (meaning it goes beyond recommending trustworthiness) but also on the overall level of trust in the network of the involved parties. La Rochefoucauld highlighted that when

1. Original quotation in French: La confiance ne nous laisse pas tant de liberté, ses règles sont plus étroites, elle demande plus de prudence et de retenue, et nous ne sommes pas toujours libres d'en disposer: il ne s'agit pas de nous uniquement, et nos intérêts sont mêlés d'ordinaire avec les intérêts des autres. Elle a besoin d'une grande justesse pour ne livrer pas nos amis en nous livrant nous-mêmes, et pour ne faire pas des présents de leur bien dans la vue d'augmenter le prix de ce que nous donnons.

one recommends another, they should be aware that the outcome of their recommendation will reflect upon their trustworthiness and reputation since they are partly responsible for this outcome. Benjamin Franklin noted about recommendations that each time he made a recommendation, his recommending trustworthiness was impacted: "in consequence of my crediting such recommendations, my own are out of credit" [6]. However, his letter underlines that still he had to make recommendations about not very well-known parties because they made the request and not making recommendations could have upset them. This is in line with Covey's "Emotional Bank Account" [7,8], where any interaction modifies the amount of trust between the interacting parties and can be seen as favor or disfavor – deposit or withdrawal. As Romano underlined in her thesis, there are many definitions of trust in a wide range of domains [9], for example, psychology, economics, or sociology. In this chapter, we use Romano's definition of trust, which is supposed to integrate many aspects of previous work on trust research:

"Trust is a subjective assessment of another's influence in terms of the extent of one's perceptions about the quality and significance of another's impact over one's outcomes in a given situation, such that one's expectation of, openness to, and inclination toward such influence provide a sense of control over the potential outcomes of the situation." [9]

In social research, there are three main types of trust: interpersonal trust, based on the outcomes of past interactions with the trustee; dispositional trust, provided by the trustor's general disposition towards trust, independent of the trustee; and system trust, provided by external means such as insurance or laws [10]. Depending on the situation, a high level of trust in one of these types can become sufficient for the trustor to make the decision to trust. When there is insurance against a negative outcome, or when the legal system acts as a credible deterrent against undesirable behavior, it means that the level of system trust is high and the level of risk is negligible – therefore the levels of interpersonal and dispositional trust are less important. It is usually assumed that by knowing the link to the real-world identity, there is insurance against harm that may be done by this entity: in essence, this is security based on authenticated identity and legal recourse. In this case, the level of system trust seems to be high but one may argue that in practice the legal system does not provide a credible deterrent against undesirable behaviour (it makes no sense to sue someone for a single spam email, as the effort expended to gain redress outweighs the benefit).

The information on the outcomes of the past interactions with the trustee that are used for trust can come from different sources. First, the information on the outcomes may be based on direct observations: when the trustor has directly interacted with the requesting trustee and personally experienced the observation. Another type of observation is when a third-party observes itself an interaction between two parties and infers itself the type of outcome. Another source of information may be specific recommenders who report to the trustor the outcomes of interactions that have not been directly observed by the trustor but by themselves or other recommenders. In this case, care must be taken not to count twice or many more times the same outcomes reported by different recommenders. Finally, reputation is another source of trust information but more difficult to analyze because generally it is not exactly known who the recommenders are and the chance to count many times the same outcomes of interactions is higher. As said in the introduction, reputation may be biased by faked evidence or other controversial influencing means. Reputation evidence is the riskiest type of evidence to process. When the evidence recommender is known, it is possible to take into account the recommender trustworthiness. Since some recommenders are more or less likely to produce good recommendations, even malicious ones, the notion of recommending trustworthiness mitigates the risk of bad or malicious recommendations. Intuitively, recommendations must only be accepted from senders that the local entity trusts to make judgments close to those that it would have made about others. We call the trust in a given situation, the trust context. For example, recommending trustworthiness happens in the context of trusting the recommendation of a recommender. Intuitively, recommendations must only be accepted from senders that the local entity trusts to make judgments close to those that it would have made about others. In the remainder of this chapter, we define reputation as follows:

Reputation is the subjective aggregated value, as perceived by the requester, of the assessments by other people, who are not exactly identified, of some quality, character, characteristic or ability of a specific entity with whom the requester has never interacted with previously.

To be able to perceive the reputation of an entity is only one aspect of reputation management. The other aspects of reputation management for an entity consist of:

- Monitoring the entity reputation as broadly as possible in a proactive way;
- Analyzing the sources spreading the entity reputation;
- Influencing the number and content of these sources to spread an improved reputation.

Therefore, reputation management involves some marketing and public relations actions. Reputation management may be applied to different types of entities: personal reputation management, which is also called

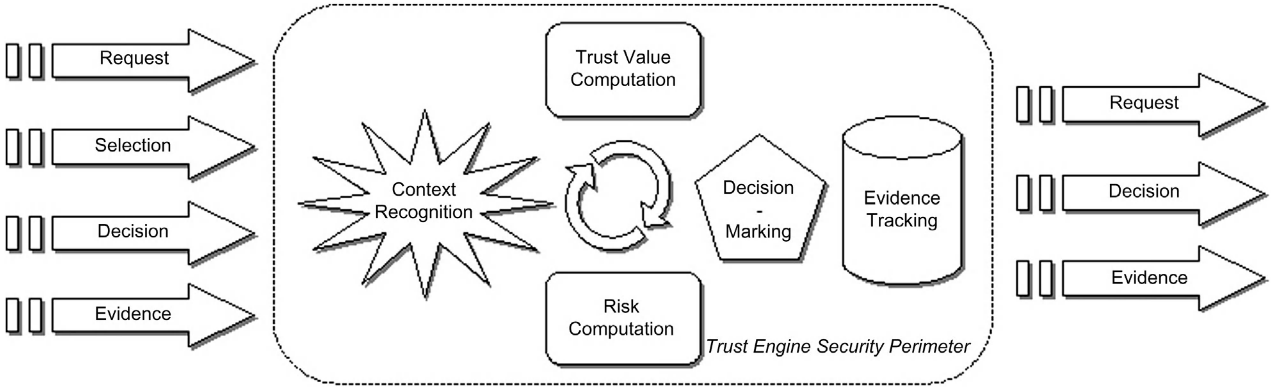

FIGURE 65.2 High-level components of a computational trust engine.

"personal branding" [11], business reputation management... It is now common for businesses to employ full time staff to influence the company's reputation via the traditional media channels. Politicians and stars also make use of public relations services. For mass people, in the past few media were available to easily retrieve people information, however as more and more people use the Web and leave digital traces, it now becomes possible to find information about any Web user via Google. For example, in a recent survey of hundred executive recruiters [12], 77% of these executive recruiters declared to use search engines to learn more about candidates.

3. REPUTATION APPLIED TO THE COMPUTING WORLD

Trust engines, based on computational models of the human notion of trust, have been proposed to make security decisions on behalf of their owner. For example, the EU-funded SECURE project [13] has built a generic and reusable trust engine that each computing entity would run. These trust engines allow the entities to compute levels of trust based on sources of trust evidence, that is, knowledge about the interacting entities: local observations of interaction outcomes or recommendations. Based on the computed trust value and given a trust policy, the trust engine can decide to grant or deny access to a requesting entity. Then, if access is given to an entity, the actions of the granted entity are monitored and the outcomes, positive or negative, are used to refine the trust value. The computed trust value represents the interpersonal trust part and is generally defined as follows:

- *A trust value is a non-enforceable estimate of the entity's future behavior in a given context based on past evidence.*
- *A trust metric consists of the different computations and communications that are carried out by the trustor (and his/her network) to compute a trust value in the trustee.*

Figure 65.2 depicts the high-level view of a computational trust engine called. This occurs when:

- A requested entity has to decide what action should be taken due to a request made by another entity, the requesting entity;
- The decision has been decided by the requested entity;
- Evidence about the actions and the outcomes is reported;
- The trustor has to select a trustee among several potential trustees.

A number of sub-components are used for the above cases:

- A component that is able to recognize the context, especially to recognize the involved entities. Depending on the confidence level in recognition of the involved entities, for example, the face has only been recognized with 82% of confidence, this may impact the overall trust decision. Context information may also consist of the time, the location and the activity of the user [14];
- Another component that can dynamically compute the trust value, that is, the trustworthiness of the requesting entity based on pieces of evidence (for example, direct observations, recommendations or reputation);
- A risk module that can dynamically evaluate the risk involved in the interaction based on the recognized context; risk evidence is also needed.

The chosen decision should maintain the appropriate cost/benefit ratio. In the background, another component is in charge of gathering and tracking evidence: recommendations, comparisons between expected outcomes of

the chosen actions and real outcomes... This evidence is used to update risk and trust information. Thus, trust and risk follow a managed life-cycle.

Depending on dispositional trust and system trust, the weight of the trust value in the final decision may be small. The level of dispositional trust may be set due to two main facts. First, the user manually sets a general level of trust, which is used in the application to get the level of trust in entities, independently of the entities. Secondly, the current balance of gains and losses is very positive and the risk policy allows any new interactions as long as the balance is kept positive. Marsh uses the term "basic trust" [15] for dispositional trust; it may also be called self-trust.

Generally, as introduced by Rahman and Hailes [16], there are two main contexts for the trust values: "direct", which is about the properties of the trustee; and "recommend", which is the equivalent to recommending trustworthiness. In their case, recommending trustworthiness is based on consistency on the "semantic distance" between the real outcomes and the recommendations that have been made. The default metric for consistency is the standard deviation based on the frequency of specific semantic distance values: the higher the consistency, the smaller the standard deviation and the higher the trust value in recommending trustworthiness.

As said in the previous section, another source for trust in human networks consists of real-world recourse mechanisms, such as insurance or legal actions. Traditionally, it is assumed that if the actions made by a computing entity are bound to a real-world identity, the owner of the faulty computing entity can be brought to court and reparations are possible. In open environment with no unique authority, the feasibility of this approach is questionable. An example where prosecution is ineffective occurs when email spammers do not mind to move operations abroad where anti-spam laws are less developed to escape any risk of prosecution. It is a fact that worldwide there are multiple different jurisdictions. Therefore, security based on the authenticated identity may be superfluous. Furthermore, in the first place, there is the question of which authority is in charge of certifying the binding with the real-world identity, since there are no unique global authorities. "Who, after all, can authenticate US citizens abroad? The UN? Or thousands of pair wise national cross-certifications?" [17].

More importantly, is authentication of the real-world identity necessary to be able to use the human notion of trust? Indeed, a critical element for the use of trust is to retrieve trust evidence on the interacting entities but trust evidence does not necessarily consist of information about the real-world identity of the owner: trust evidence may simply be the count of positive interactions with a pseudonym as defended in [13]. As long as the interacting computing entities can be recognized, direct observations and recommendations can be exchanged in order to build trust, interaction after interaction. This level of trust can be used for trusting decisions. Thus, trust engines can provide dynamic protection without the assumption that real-world recourse mechanisms, such as legal recourse, are available in case of harm.

The terms trust/trusted/trustworthy, which appear in the traditional computer science literature, are not grounded on social science and often correspond to an implicit element of trust. For example, we have already mentioned above the use of trusted-third-parties, called CAs, which are common in PKI infrastructures. Another example is Trusted Computing [18], whose goal is to create enhanced hardware by using cost effective security hardware (more or less comparable to a smart card chip) that acts as the "root of trust". *They are trusted* means that they are assumed to make use of some (strong) security protection mechanisms. Therefore they can/must implicitly be blindly trusted and cannot fail. This cannot address security when it is not known who or whether or not to blindly trust. The term "trust management" has been introduced in computer security by Blaze et al. [19] but others have argued that their model still relies on an implicit notion of trust because it only describes "a way of exploiting established trust relationships for distributed security policy management without determining how these relationships are formed" [20]. There is a need for trust formation mechanisms from scratch between two strangers. Trust engines build trust explicitly based on evidence either personal, reported by known recommenders or through reputation mechanisms.

As said in the previous section, reputation is different than a recommendation who is made by a known specific entity. However, in the digital world, it is still less easy to exactly certify the identity of the recommender and in many cases the recommender can only be recognized up to some extent. The entity recognition occurs with the help of the context recognition module and the level of confidence in recognition may be taken into account in the final trust computation, for example, as done in advanced computational trust engines [13]. In the remainder of this chapter, for simplicity's sake since this chapter focuses on reputation rather than trust, we assume that each entity can be recognized with a perfect confidence level in recognition. Thus, we obtain the following two layers depicted in Figure 65.3, the identity management layer and the reputation management layer. In these layers, although we mention the world identity, we do not mean that the real-world identity behind each entity is supposed to be certified, we assume that it is sufficient to recognize the entity at a perfect level of confidence in recognition, for example, if a recommendation is received from an eBay account, it is sure that it comes from this

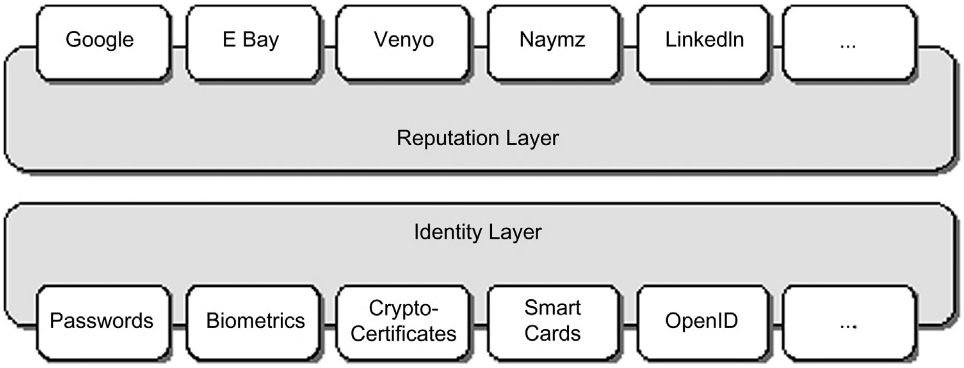

FIGURE 65.3 Identity management and reputation management layers.

account and that it is not spoofed. There are different rounded rectangles at the top of the reputation layer that represent a few of the different reputation services detailed in Section 5. There are also a number of rounded rectangles below the identity layer that represent the different types of authentication schemes that can be used to recognize an entity. Although password-based or OpenID[2]-based [21] authentication may be less secure than multi-modal authentication combining biometrics, smart cards and crypto-certificates [13], since we assume that the level of confidence in recognition is perfect as said above, the different identity management technologies are abstracted to a unique identity management layer for the remainder of the chapter.

As presented in the previous section, reputation management goes beyond mere reputation assessment and encompasses monitoring, analysis and influence of reputation sources. It is the reason that we introduce the following categories, depicted in Figure 65.4, for online reputation services:

- Reputation Calculation: Based on evidence gathered by the service, the service either computes a value representing the reputation of a specific entity or simply presents the reputation information without ranking.
- Reputation Monitoring, Analysis and Warnings: The service monitors Web-based media (Web sites, blogs, social networks, digitalized archived of paper-based press and trademarks...) to detect any information impacting the entity reputation and warns the user in case of important changes.
- Reputation Influencing, Promotion and Rewards: The service takes actions to influence the perceived reputation of the entity. The service actively promotes the entity reputation, for example, by publishing Web pages carefully designed to reach a high rank in major search engines or paid online advertisements, such as, Google AdWords. Users reaching a higher reputation may gain other rewards than promotion, such as, discounts. Based on the monitoring services analysis, the service may be able to list the most important reputation sources and allow the users to influence these sources. For example, in a 2006 blog bribe case, it has been reported that free laptops preloaded with a new commercial operating system have been shipped for free to the most important bloggers in the field of consumer-oriented software in order to improve the reputation of the new operating software.
- Interaction Facilitation and Follow-up: The service provides an environment to facilitate the interaction and its outcome between the trustor and the trustee. For example, eBay provides the online auction system to sellers and buyers as well as monitors the follow-up

FIGURE 65.4 Online reputation management services categories.

2. Please refer to Chapter 15 on Identity Management to learn more about OpenID.

of the commercial transaction between the buyer and the seller.

- Reputation Certification and Assurance: That type of service is closer to the notion of system trust than the human notion of reputation because it relies on externals means to avoid ending up in a harmful situation. For example, an insurance is paid as part of a commercial transaction. These services might need the certification of the link between the entity and its real-world identity in case of prosecutions. Our assumption does not hold for the services that require that kind of links but that category of services had to be covered because a few services surveyed below make use of them.
- Fraud Protection, Mediation, Cleaning and Recovery: The above promotion services aim at improving the ranking of reputation information provided by the user rather than external information provided by third-parties. However, even if external information is hidden behind more controlled information, it can still be found. It is the reason that some services try to force the owners of the external sites hosting the damaging reputation information to delete the damaging information. Depending on where the server is located, it is more or less difficult to achieve. It may be as simple as filling an online form on the site hosting the defaming information to contact the technical support employee who will check if the information is really problematic. In the case of a reluctant administrator, lawyers or mediators specialized in online defamation laws have to be commissioned and it is more or less easy depending on the legislation in the country hosting the server. Generally, in countries with clear defamation laws, the administrators prefer deleting the information rather than going into a lengthy and costly legal process. Depending on the mediation and the degree of defamation, the host may have to add an apology in place of the defaming information, pay a fine or more… Fraud protection is also needed against reputation calculation attacks. There are different types of attacks that can be carried out to flaw reputation calculation results [13]. Section 4 presents the state of the art of attack-resistant reputation computation.

4. STATE OF THE ART OF ATTACK—RESISTANT REPUTATION COMPUTATION

In most commercial reputation services surveyed in Section 5, the reputation calculation does not take into account the attack-resistance of their algorithm. It is a pity because there are many different types of attacks that can be carried out, especially at the identity level. In addition, most of these reputation algorithms correspond more to a trust metric algorithm rather than reputation as we have defined it in Section 2 because they aggregate ratings submitted by recommenders or the rater itself rather than rely on evidence whose recommenders are unknown. Based on these ratings that we can consider as either direct observations or recommendations, the services compute a reputation score that we can consider as a trust value, generally represented on a scale from 0 to 100% or from 0 to 5 stars. The exact reputation computation algorithm is not publicly disclosed by all services providers and it is difficult to estimate the attack-resistance of each of these algorithms without their full specification. However, it is clear that many of these algorithms do not provide a high-level of attack-resistance for the following reasons:

- Besides eBay, where each transaction corresponds to a very clear trust context with quite well authenticated users and a real transaction that is confirmed by real money transfers, most services occur in a decentralized environment and allow for the rating of non-confirmed transactions (without any real evidence that the transaction really happened, and even worse by anonymous users).
- Still eBay experiences difficulties with its reputation calculation algorithm. In fact, eBay has recently changed its reputation calculation algorithm: the sellers on eBay are not allowed anymore to leave unfavorable or neutral messages about buyers to diminish the risk that buyers fear to leave negative feedbacks due to retaliatory negative feedback from the sellers. Finally, accounts on eBay, which are protected by passwords, may be usurped. According to Twigg and Dimmock [22], a trust metric is γ-resistant if more than γ nodes must be compromised for the attacker to successfully drive the trust value. For example, Rahman and Hailes' [16] trust metric is not γ-resistant for $\gamma > 1$ (a successful attack needs only one victim).

In contrast to the centralized environment of eBay, in decentralized settings there are a number of specific attacks. First, real-world identities may form an alliance and use their recommendation to undermine the reputation of entities. On one hand, this may be seen as collusion. On the other hand, one may argue that real-world identities are free to vote as they wish. However, the impact is greater online. Even if more and more transactions and interactions are traced online, the majority of transactions and interactions that happen in the real world are not reported online. Due to the limited number of traced transactions and interactions, a few faked transactions and interactions can have a high impact on the computed reputation and it is not fair.

Second, we focus below on attacks based on vulnerabilities in the identity approach and subsequent use of these vulnerabilities (see checklist: "An Agenda For

Action For Implementing A Network Vulnerability Assessment"). The vulnerabilities may have different origins, for example, technical weaknesses in the authentication mechanism. These attacks commonly rely on the possibility of identity multiplicity: meaning that a real-world identity uses many digital pseudonyms. A very well-known identity multiplicity attack in the field of computational trust is Douceur's Sybil attack [23]. Douceur argues that in large scale networks where a centralized identity authority cannot be used to control the creation of pseudonyms, a powerful real-world entity may create as many digital pseudonyms as it wishes and recommend one of these pseudonyms in order to fool the reputation calculation algorithm. This is especially important in scenarios where the possibility to use many pseudonyms is facilitated, for example, in scenarios where pseudonyms creation is provided for better privacy protection.

An Agenda for Action for Implementing a Network Vulnerability Assessment

The key areas examined in this checklist include (Check All Tasks Completed):

_____**1.** Unique user ID and confidential password required.
_____**2.** Additional identification required for remote access.
_____**3.** Help screen access available to logged-on users only.
_____**4.** Last session date and time message back to user at sign-on time.
_____**5.** Exception reports for disruptions in either input or output.
_____**6.** Session numbers for users/processors that are not constantly logged in.
_____**7.** Notification to users of possible duplicate messages.
_____**8.** Threshold of errors and consequential retransmission on the network related to management via automatic alarms.
_____**9.** Encryption requirements.
_____**10.** Encryption key management controls.
_____**11.** Message Authentication Code requirements for nonencrypted sensitive data transmission.
_____**12.** System authentication at session start-up (wiretap controls).
_____**13.** Confirmation of host log-off to prevent line grabbing.
_____**14.** Downloading controls for connected intelligent workstations.
_____**15.** User priority designation process.
_____**16.** Transaction handling for classified communications.
_____**17.** Trace and snapshot facilities requirements.
_____**18.** Log requirements for sensitive messages
_____**19.** Alternate path requirements between nodes
_____**20.** Contingency plans for hardware as well as all usual system requirements.
_____**21.** Storage of critical messages in redundant locations.
_____**22.** Packet recovery requirements
_____**23.** Physical access for workstations when units are not in use.
_____**24.** Control units, hubs, routers, cabinets secured.
_____**25.** Environmental control critical requirements.
_____**26.** Segregation for sections of the network that are deemed "untrustworthy."
_____**27.** Gateway identification for authorized nodes.
_____**28.** Automatic disable of a user/account, line or port if evidence an attack is underway.
_____**29.** Naming convention to distinguish test messages from production.
_____**30.** User switching application controls.
_____**31.** Time-out reauthorization requirements.
_____**32.** Password changes (time/length/history) requirements.
_____**33.** Encryption requirements for passwords, security parameters, encryption keys, tables, etc.
_____**34.** Shielding requirements for fiber-optic lines.
_____**35.** Controls to prevent wiretapping
_____**36.** Reporting procedures for all interrupted telecommunication sessions
_____**37.** Identification requirements for station/ terminal access connection to network.
_____**38.** Printer control requirements for classified information.
_____**39.** Appropriate "welcome" connection screens
_____**40.** Dial-up access control procedures.
_____**41.** Anti-daemon dialer controls
_____**42.** Standards for equipment, applications, protocols, operating environment
_____**43.** Help desk procedures and telephone numbers.
_____**44.** Protocol converters and access method converters dynamic change control requirements
_____**45.** LAN administrator responsibilities
_____**46.** Control requirements to add nodes to the network
_____**47.** Telephone number change requirements
_____**48.** Automatic sign-on controls
_____**49.** Telephone trace requirements
_____**50.** FTP access controlled
_____**51.** Are patches tested and applied?
_____**52.** Software distribution current
_____**53.** Employee policy awareness
_____**54.** Emergency incident response plan/procedure
_____**55.** Internal applications control
_____**56.** Proper control of the development environment
_____**57.** Software licensing compliance review
_____**58.** Portable device (laptop/notebook/PDA) handling procedures.

_____**59.** Storage and disposal of sensitive data/information
_____**60.** Default password controls and settings
_____**61.** Review of off-site storage for disaster recovery resources
_____**62.** Unnecessary services disabled
_____**63.** Client server data transfer analyzed and secured
_____**64.** Restrict telnet and r-commands (rlogin, rsh, etc.)
_____**65.** Configuration management procedures
_____**66.** Tracking port scans
_____**67.** Review monitoring responsibilities
_____**68.** Separation between test and production environment
_____**69.** Strong dial-in authentication
_____**70.** System administrator training
_____**71.** Voice system protection procedures
_____**72.** Tunneling for all remote access (inbound or outbound)
_____**73.** Encryption of laptops
_____**74.** Management awareness
_____**75.** Program and system change control procedures
_____**76.** Open "inbound" modem access for vendor support
_____**77.** Modem usage policy
_____**78.** Incident event coordination (procedures)
_____**79.** Intrusion detection system (IDS) implementation and monitoring
_____**80.** Monitoring Web site from attack (internal and external)
_____**81.** Domain Name Server monitoring
_____**82.** Hardware maintenance requirements
_____**83.** Hard drive repair, maintenance, and disposal procedures
_____**84.** BIOS (Basic Input/Output System) boot order
_____**85.** E-mail content policy and monitoring
_____**86.** E-mail forwarding policy (hopping)
_____**87.** Spamming controls and testing procedures
_____**88.** Employee termination and credential disablement
_____**89.** After-hours sign-in logs
_____**90.** Network sniffer policy, procedures, and monitoring
_____**91.** Validity of e-mail accounts
_____**92.** Background checks before hiring
_____**93.** Administrator accounts and password controls
_____**94.** Time synchronization procedures
_____**95.** Establishment of a Security Committee
_____**96.** Testing process for LAN applications
_____**97.** Business unit security person designated
_____**98.** Log and review of all Administrator changes
_____**99.** Review and resolution of past audit comments
_____**100.** Audit logs secured

In his PhD thesis, Levien [24] says that a trust metric is attack-resistant if the number of faked pseudonyms, owned by the same real-world identity and that can be introduced, is bounded. Levien argues that to mitigate the problem of Sybil-like attacks it is required to compute "a trust value for all the nodes in the graph at once, rather than calculating independently the trust value independently for each node". Another approach proposed to protect against the Sybil attack is the use of mandatory "entry fees" [25] associated with the creation of each pseudonym. This approach raises some issues about its feasibility in a fully decentralized way and the choice of the minimal fee that guarantees protection. Also, "more generally, the optimal fee will often exclude some players yet still be insufficient to deter the wealthiest players from defecting" [25]. An alternative to entry fees may be the use of once in a lifetime (1L [25]) pseudonyms, where an elected party per "arena" of application is responsible to certify only 1L to any real-world entity, which possesses a key pair bound to this entity's real-world identity. The technique of blind signature [26] is used to keep the link between the real-world identity and its chosen pseudonym in the arena unknown to the elected party. However, there are still two unresolved questions about this approach: how the elected party is chosen and how much the users would agree to pay for this approach. More importantly, a Sybil attack is possible during the voting phase, so the concept of electing a trusted entity to stop Sybil attacks does not seem practical. However, relying on real money turns the trust mechanism into a type of system trust where the use of reputation becomes almost superfluous. In the real world, tax authorities are likely to require traceability of money transfers, which would completely break privacy. Thus, when using pseudonyms, another means must be present to prevent users from taking advantage of the fact that they can create as many pseudonyms as they wish.

"Trust transfer" [13] has been introduced to encourage self-recommendations without attacks based on the creation and use of a large number of pseudonyms owned by the same real-world identity. In a system where there are pseudonyms that can potentially belong to the same real-world entity, a transitive trust process is open to abuse. Even if there is a high recommendation discounting factor due to recommending trustworthiness, the real-world entity can diminish the impact of this discounting factor by sending a huge number of recommendations from his/her army of pseudonyms in a Sybil attack. When someone recommends another person, he/she has influence over the potential outcome of interaction between this person

and the trustor. The inclination of the trustor with regard to this influence "provides a goal-oriented sense of control to attain desirable outcomes" [9]. So, the trustor should also be able to increase/decrease the influence of the recommenders according to his/her goals. Moreover, according to Romano, trust is not multiple constructs that vary in meaning across contexts but a single construct that varies in level across contexts. The overall trustworthiness depends on the complete set of different domains of trustworthiness. This overall trustworthiness must be put in context: it is not sufficient to strictly limit the domain of trustworthiness to the current trust context and the trustee; if recommenders are involved, the decision and the outcome should impact their overall trustworthiness according to the influence they had. Kinateder et al. [27] also take the position that there is a dependence between different trust contexts. For example, a chef known to have both won cooking awards and murdered people may not be a trustworthy chef after all. Trust transfer introduces the possibility of a dependence between trustworthiness and recommending trustworthiness. Trust transfer relies on the following assumptions:

- The trust value is based on direct observations or recommendations of the count of event outcomes from recognized entities (for example, the outcome of an eBay auction transaction with a specific seller from a specific buyer recognized by their eBay account pseudos)
- A pseudonym can neither be compromised nor spoofed; an attacker can neither take control of a pseudonym nor send spoofed recommendations; however, everyone is free to introduce as many pseudonyms as they wish;
- All messages are assumed to be signed and time stamped.

Trust transfer implies that recommendations cause trust on the trustor (*T*) side to be transferred from the recommender (*R*) to the subject (*S*) of the recommendation. A second effect is that the trust on the recommender side for the subject is reduced by the amount of transferred trustworthiness. If it is a self-recommendation, that is, recommendations from pseudonyms belonging to the same real-world identity, then the second effect is moot, as it does not make sense for a real-world entity to reduce trust in his/her own pseudonyms. Even if there are different trust contexts (such as trustworthiness in delivering on time or recommending trustworthiness), each trust context has its impact on the single construct trust value: they cannot be taken separately for the calculation of the single construct trust value. A transfer of trust is carried out if the exchange of communications depicted in Figure 65.5 is successful. A local entity's Recommender Search Policy (*RSP*) dictates which contacts can be used as potential recommenders. Its Recommendation Policy (*RP*) decides which of its contacts it is willing to recommend to other entities, and how much trust it is willing to transfer to an entity. Trust Transfer (in its simplest form) can be decomposed into 5 steps:

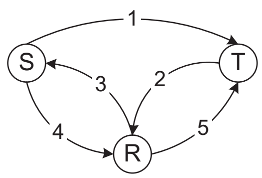

FIGURE 65.5 Trust transfer process.[3]

1. The subject requests an action, requiring a total amount of trustworthiness *TA* in the subject, in order for the request to be accepted by the trustor; the actual value of *TA* is contingent upon the risk acceptable to the user, as well as dispositional trust and the context of the request; so the risk module of the trust engine plays a role in the calculation of *TA*;
2. The trustor queries its contacts, which pass the *RSP*, in order to find recommenders willing to transfer some of their positive event outcomes count to the subject. Recall that trustworthiness is based on event outcomes count in trust transfer;
3. If the contact has directly interacted with the subject and the contact's *RP* allows it to permit the trustor to transfer an amount $(A \leq TA)$ of the recommender's trustworthiness to the subject, the contact agrees to recommend the subject. It queries the subject whether it agrees to lose *A* of trustworthiness on the recommender side;
4. The subject returns a signed statement, indicating whether it agrees or not;
5. The recommender sends back a signed recommendation to the trustor, indicating the trust value it is prepared to transfer to the subject. This message includes the signed agreement of the subject.

Both the *RSP* and *RP* can be as simple or complex as the application environment demands. The trust transfer process is illustrated in Figure 65.6 where the subject requests an action, which requires *10* positive outcomes. We represent the trust value as a tree of *(s,i,c)*-triples, corresponding to a mathematical event structure [28]: an event outcome count is represented as a *(s,i,c)*-triple, where *s* is the number of events that supports the

3. In this type of figure, the circles represent the different involved entities: *S* corresponds to the sender, which is the subject of the recommendation and the requester; *T* is the trustor, which is also the target; and *R* is the recommender. The directed black arrows indicate a message sent from one entity to another. The arrows are chronologically ordered by their number.

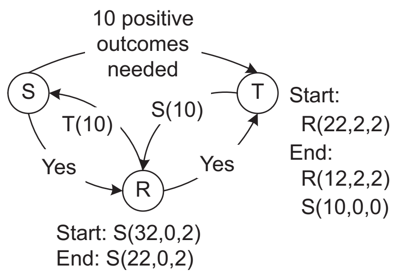

FIGURE 65.6 Trust transfer process example.[4]

outcome, *i* is the number of events that have no information or are inconclusive about the outcome and *c* is the number of events that contradict the expected outcome. This format takes into account the element of uncertainty via *i*.

The *RSP* of the trustor is to query a contact to propose to transfer trust if the *balance (s-i-c)* is strictly greater than *2TA*. This is because it is sensible to require that the recommender remains more trustworthy than the subject after the recommendation. The contact, having a balance passing the *RSP* (*s-i-c = 32-0-2 = 30)*, is asked by the trustor whether he/she wants to recommend *10* good outcomes. The contact's *RP* is to agree to the transfer if the subject has a trust value greater than *TA*. The balance of the subject on the recommender's side is greater than *10 (s-i-c = 22-2-2 = 18)*. The subject is asked by the recommender whether he/she agrees *10* good outcomes to be transferred. Trustor *T* reduces its trust in recommender *R* by *10* and increases its trust in subject *S* by *10*. Finally, the recommender reduces her/his trust in the subject by *10*.

The recommender could make requests to a number of recommenders until the total amount of trust value is reached (the search requests to find the recommenders are not represented in the figures). For instance, in the previous example, two different recommenders could be contacted, with one recommending *3* good outcomes and the other one *7*.

A recommender chain in trust transfer is not explicitly known to the trustor. The trustor only needs to know his/her contacts who agree to transfer some of their trustworthiness. This is useful from a privacy point of view since the full chain of recommenders is not disclosed. This is in contrast to other recommender chains such as public keys web of trust [29]. Because we assume that the entities cannot be compromised, we leave the issue surrounding the independence of recommender chains in order to increase the attack resistance of the trust metric for future work. The reason for searching more than one path is that it decreases the chance of a faulty path (either due to malicious intermediaries or unreliable ones). If the full list of recommenders must be detailed in order to be able to check the independence of recommender chains, the privacy protection is lost. This can be an application-specific design decision.

Thanks to trust transfer, although a real-world identity has many pseudonyms, the Sybil attack cannot happen because the number of direct observations (and hence, total amount of trust) remains the same on the trustor side. One may argue that it is unfair for the recommender to lose the same amount of trustworthiness as specified in his/her recommendation, moreover if the outcome is ultimately good. It is envisaged that a more complex sequence of messages can be put in place in order to revise the decrease of trustworthiness after a successful outcome. This has been left for future work, because it can lead to vulnerabilities (for example, based on Sybil attacks with careful cost/benefit analysis). The current trust transfer approach is still limited to scenarios where there are many interactions between the recommenders and where the overall trustworthiness in the network (that is, the global number of good outcomes) is large enough that there is no major impact to entities when they agree to transfer some of their trust (such as in the email application domain [13]). Ultimately, without sacrificing the flexibility and privacy enhancing potential of limitless pseudonym creation, Sybil attacks are guaranteed to be avoided.

5. OVERVIEW OF CURRENT ONLINE REPUTATION SERVICE

As explained in the previous section, most of the current online reputation services surveyed in this section do not really compute reputation as we have defined it in Section 2. Their reputation algorithms correspond more to a trust metric because they aggregate direct observations and recommendations of different users rather than base their assessment on evidence from a group of an unknown number of unknown users. However, one may consider that these services present reputations to their users if we assume that their users do not take the time to understand how it was computed and who made the recommendations.

The remainder of this section starts by surveying the main online reputation services and finishes by a recapitulating table. If not mentioned otherwise, the reputation services do not require the users to pay a fee.

eBay

Founded in 1995, eBay has been a very successful online auction market place where buyers can search for products offered by sellers and buy them either directly or after an auction. After each transaction, the buyers can

4. In this figure, an entity *E* associated with a SECURE triple *(s,i,c)* is indicated by *E(s,i,c)*.

rate the transaction with the seller as "positive", "negative" or "neutral". Since May 2008, the sellers have only the choice to rate the buyer experience as "positive" or nothing else. Short comments of maximum 80 characters can be left with the rating. Their reputation is based on the number of positive and negative ratings that are aggregated in the Feedback Score as well as the comments if the user reads them. Buyers or sellers can affect each other's Feedback Score by only one point per week. Each positive rating counts for 1 point and each negative counts for -1 point. The balance of points is calculated at the end of the week and if the Feedback Score is increased by 1 if the balance is positive or decreased by 1 if the balance is negative. Buyers can also leave anonymous "Detailed Seller Ratings" composed of different criteria, such as, "Item as described", "Communication", "Shipping Time"… displayed as a number of stars from 0 to 5 stars. Different image icons are also displayed to quickly estimate the reputation of the user, for example, a star whose color depends on the Feedback Score. After 90 days, detailed item information is removed. From a privacy point of view, on one hand, it is possible to use a pseudonym, on the other hand, a pretty exhaustive list of what has been bought is available, which is quite a privacy concern. There are different "Insertion" and "Final Value" fees depending on the item type. eBay addresses the different reputation service categories as follows:

- Reputation Calculation: As detailed above, reputation is computed based on transactions that are quite well tracked, which is important to avoid faked evidence. However, eBay's reputation calculation has still some problems, for example: as explained above, the algorithm had to be changed recently; the value of the transaction is not taken into account at time of Feedback Score update (a good transaction of 10 Euros should count less than a good transaction of 10 kEuros); it is limited to the e-commerce application domain…
- Monitoring, Analysis and Warnings: eBay does not monitor the reputation of its users outside of its service.
- Influencing, Promotion and Rewards: eBay rewards its users through their public FeedBack Score and their associated icons images. However, eBay does not promote the user reputation outside of its system and does not facilitate this promotion due to a strict access to its full evidence pool although some Feedback Score data can be accessed through eBay software developer Application Programming Interface (API).
- Interaction Facilitation and Follow-up: eBay provides a comprehensive Web-based site to facilitate online auctions between buyers and sellers including a dedicated messaging service and advanced tools to manage the auction. The follow-up based on the Feedback Score is pretty detailed.
- Reputation Certification and Assurance: eBay does not certify a user reputation per se but given its leading position eBay Feedback Score can be considered, to some extent, as some certified reputation evidence.
- Fraud Protection, Mediation, Cleaning and Recovery: eBay facilitates the communication between the buyer and the seller as well as a dispute console with eBay customer support employees. A rating and comment cannot be deleted since the "Mutual Feedback Withdrawal" has been removed. In extreme cases, if the buyer had paid through PayPal, which is now part of eBay, the item might be refunded after some time if the item is covered and depending on the item price. Finally, eBay works with a number of escrow services that act as a third-party who do not deliver the product until the payment is made. Again, if such third-party services are used, the use of reputation is less useful because these third-party services decrease a lot the risk of a negative outcome. eBay does not offer to clean the reputation outside of its own Web site.

Opinity

Founded in 2004, Opinity [30] has been one of the first commercial effort to build decentralized online reputation for users in all contexts beyond eBay's limited e-commerce context. However, at time of writing, that is July 2008, Opinity seems has been inactive for a while. After creating an account, the users had the possibility to specify their login and passwords of other Web sites, especially, eBay, in order to retrieve and consolidate all evidence in the user's Opinity account. Of course, asking the users to provide their passwords was risky and seems not a good security practice. Another safer option was for the users to put hidden text in the HTML pages of their external services, such as, eBay. Opinity was quite advanced at the identity layer as it supported OpenID and Microsoft Cardspace as mentioned in. In addition, Opinity could retrieve professional or education background and verify it to some extent using public listings or for a fee. Opinity users could rate other users in different contexts ("plumbing" or "humor"). Opinity addressed the different reputation service categories as follows:

- Reputation Calculation: The reputation was calculated based on all the above evidence sources and could be accessed by other Opinity partner sites. The reputation could be focused to a specific context called a reputation category.
- Monitoring, Analysis and Warnings: Opinity did not really cover this category of services as most evidence

was pointed out by the users as they were adding the external accounts that they own.

- Influencing, Promotion and Rewards: Opinity had the base “Opinity Reputation Score” and it was possible to include a Web badge representation that reputation on external Web sites.
- Interaction Facilitation and Follow-up: Opinity did not really cover this category of services besides the fact that users could mutually decide to disclose more detail of their profile via the “Exchange Profile” feature.
- Reputation Certification and Assurance: As said above, Opinity certified educational, personal or professional information to some extent via public listings or for a fee to check the information provided by the users.
- Fraud Protection, Mediation, Cleaning and Recovery: One Opinity’s relevant feature in this category is its reputation algorithm. However, it is not known how strong this algorithm was resistant to attacks, for example, against a user who creates many Opinity accounts and use them to rate well a main account. Another relevant feature was that users could appeal bad reviews via a formal dispute process. Opinity did not offer to clean the reputation outside of its own Web site.

Rapleaf

Founded in 2006, Rapleaf [31] is the first built reputation about email addresses. Any Rapleaf user was able to rate any other email address, which may open to defamation or other privacy issues because the users behind the email addresses may not have given their consent. If the email address to be rated had never been rated before, Rapleaf was informing the potential rater that it had started crawling the Web to search for information about that email address and that once the crawling would finished it would invite the rater to add a rating. Different contexts were possible “Buyers, Sellers, Swappers and Friends”. Once a rating was entered, it could not be removed. However, new comments were possible and users could rate an email address several times. We use the past tense because at time of writing this second edition of this chapter, Rapleaf has changed its service. It does not compute and provide a public reputation score anymore. It now provides marketing data about an email addresses to paying customers willing to carry out emails marketing campaigns, maybe due to the issues depicted below.

Rapleaf was also crawling online social networks and any external profile linked to the searched email address was added to the Rapleaf profile. The email address owners could also add the other email addresses that they own to their profile to provide a unified view of their reputation. Unfortunately, Rapleaf’s investors were also involved in two other related services: Upscoop.com that allows users to import their list of social network friends after disclosing their online social networks passwords (which is a risky practice as already mentioned above) and see in which other social networks their friends are subscribed too (at time of writing the first version of this chapter Upscoop had already information about over 400 millions profiles); Trustfuse.com is a third business that retrieves profile information for marketing businesses who submit their lists of email addresses to Trustfuse. Officially, Rapleaf was not selling its base of email addresses. However, according to their August 2007 policy, “information captured via Rapleaf could be used to assist TrustFuse services. Additionally, information collected by TrustFuse during the course of its business could also be displayed on Rapleaf for given profiles searched by e-mail address”, which was quite worrisome from a privacy point of view and made a scandal at this time. In its first version, Rapleaf addressed the different reputation service categories as follows:

- Reputation Calculation: There is the “Rapleaf Score” that takes into account ratings evidence in all contexts as well as how the users have rated others and their social network connections. Unfortunately the algorithm is not public and thus its attack-resistance is unknown. In contrast to eBay, the commercial transactions reported in Rapleaf are not substantiated by other facts than the rater rating information. Thus, the chance of faked transactions is higher. Apparently, a user rating may rate several times an email address. However, a user rating only counts for once in the overall reputation of the target email address.
- Monitoring, Analysis and Warnings: Rapleaf warns the target email address when a new rating is added.
- Influencing, Promotion and Rewards: The “Rapleaf Score” can be embedded in a Web badge and displayed on external Web pages.
- Interaction Facilitation and Follow-up: At least, it is possible for the target email address to be warned of a rating and to rate back the rater.
- Reputation Certification and Assurance: There is no real feature in this category.
- Fraud Protection, Mediation, Cleaning and Recovery: There is a form that allows the owner of a particular email address to remove that email address from Rapleaf. For more important issues, such as defamation, a support email address is provided. Rapleaf does not offer to clean the reputation outside of its own Web site.

Venyo

Founded in 2006, Venyo [32] provided a worldwide people reputation index, called the Vindex, based on either

direct ratings through the user profile on Venyo Web site or indirect ratings through contributions or profiles on partner Web sites. Venyo was very privacy-friendly because it was not asking the users for their external passwords and it did not crawl the Web to present a user reputation without his or her initial consent. Unfortunately, Venyo got fewer profiles than the other services that were more aggressive and less privacy friendly and was terminated in 2009. Venyo addressed the different reputation service categories as follows:

- Reputation Calculation: Venyo's reputation algorithm is not public and therefore its attack-resistance is unknown. At time of rating, the rater specifies a value between 1 and 5 as well as keywords corresponding to the tags contextualizing the rating as depicted in Figure 65.7. The rating is also contextualized according to where the rating has been done. For example, if the rating is done from a GaultMillau restaurant blog article, the tag "restaurant recommendation" is automatically added to the list of tags.
- Monitoring, Analysis and Warnings: Venyo provides a reputation history chart as depicted in to help the users monitoring the evolution of their reputation on Venyo's and partner's Web sites. Venyo does not monitor external Web pages or information.
- Influencing, Promotion and Rewards: The Vindex allows the users to search for the most reputable users in different domains specified by tags and it can be tailored to specific locations. In addition, the Venyo Web badge can be embedded in external Web sites. There is also a Facebook plug-in to port Venyo reputation into a Facebook profile.
- Interaction Facilitation and Follow-up: The Vindex facilitates finding the most reputable user for the request context.
- Reputation Certification and Assurance: There is no Venyo feature in this category yet.
- Fraud Protection, Mediation, Cleaning and Recovery: As mentioned above, Venyo's e-reputation algorithm attack-resistance cannot be assessed because Venyo's algorithm is not public. The cleaning feature is less relevant because the users do not know who have rated them. An account may be closed if the user requests it. As said above, Venyo is more privacy-friendly than other services that request passwords or display reputation without their consent.

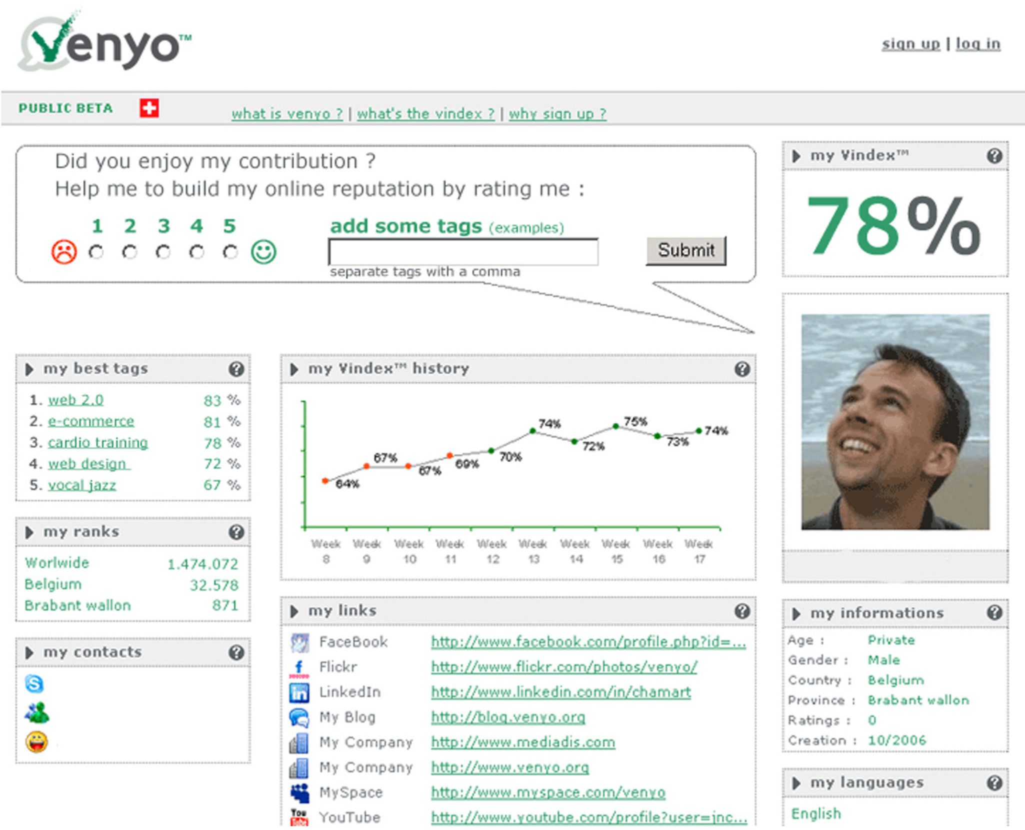

FIGURE 65.7 Venyo e-reputation user interface.

TrustPlus + Xing + ZoomInfo + SageFire

TrustPlus is another decentralized e-reputation calculation service that existed when writing the first version of this chapter but unfortunately had also to close in April 2012 before finishing the second version of this book chapter due to a business model that did not work. They left a final message on their blog web site that clearly stated that their business model did not work out well enough to be able to continue their service.

Founded in 1999, ZoomInfo is more a people (and company) search directory than a reputation services. However, ZoomInfo, with its 42 millions plus users, 3,8 millions companies and partnership with Xing.com (a business social network similar to LinkedIn.com) had formed an alliance with TrustPlus [33], which was an online reputation service founded in 2006. The main initial feature of TrustPlus was a Web browser plug-in that allowed the user to see the TrustPlus reputation of an online profile appearing on Web pages on different sites, such as, craiglist.org. At the identity layer, TrustPlus asked the users to type their external accounts passwords, for example, eBay's or Facebook's ones, to validate that they own these external accounts as well as to create their list of contacts. This list of contacts could be used to specify who among the contacts could see the detail of which transactions or ratings.

TrustPlus rating user interface and score were pretty complex. There were different contexts: a commercial transaction, a relationship and an interaction, for example, a chat or a date.

Thanks to its partnership with SageFire, which is a trusted eBay Certified Solution Provider who has access to historical archives of eBay reputation data, TrustPlus was able to display and use eBay's reputation evidence when the users agreed to link their TrustPlus account with their eBay account. TrustPlus addressed the different reputation service categories as follows:

- Reputation Calculation: TrustPlus reputation algorithm combines the different sources of reputation evidence reported to TrustPlus by its users and partner sites. However, TrustPlus reputation algorithm is not public and thus again it is difficult to assess its attack-resistance. At time of rating a commercial transaction, it is possible to specify the amount involved in the transaction, which is interesting from a computational trust point of view. Unfortunately, the risk that this transaction is faked is higher than in eBay because there is no other real facts that corroborate the information given by the rating user.
- Monitoring, Analysis and Warnings: TrustPlus warns the user when a new rating has been entered or a new request for rating has been added. However, there is no broader monitoring of the global reputation of the user.
- Influencing, Promotion and Rewards: TrustPlus provides different tools to propagate the user reputation: a Web badge that may include eBay's reputation, visibility once the TrustPlus Web browser plug-in viewer has been installed and link with the ZoomInfo directory.
- Interaction Facilitation and Follow-up: TrustPlus provides an internal messaging service that increases the tracking quality of the interactions between the rated users and the raters.
- Reputation Certification and Assurance: There is no reputation certification done by TrustPlus per se but the certification is a bit more formal when the users have chosen the option to link their eBay reputation evidence.
- Fraud Protection, Mediation, Cleaning and Recovery: As said above, the attack-resistance of TrustPlus reputation algorithm is unknown. In case of defamation or rating disputes, a "Dispute Rating" button is available in the "Explore Reputation" section of the TrustPlus site. When a dispute is initiated, the users have to provide substantiating evidence to the TrustPlus support employees via email. TrustPlus does not offer to clean the reputation outside of its own Web site.

Naymz + Trufina: Visible.Me

Founded in 2006, Naymz [34] has formed an alliance with Trufina.com, which is in charge of certifying identity and background user information. Premium features cost 9,95 $ per month at time of writing the first version of this book chapter. The users are asked for their passwords on external sites such as LinkedIn to invite their list of contacts on these external sites, which is a bad security practice as already mentioned several times above. Unfortunately, it seems that Naymz has been too aggressive concerning its emails policy and a number of users have complained to receive unsolicited emails from Naymz, for example, "I have been spammed several times over the past several weeks by a service called Naymz".[5] In 2011, Naymz has also revised its business model and changed its name to visible.me. Naymz has addressed the different reputation service categories as follows:

- Reputation Calculation: Naymz RepScore combines a surprising set of information: not only the ratings given by other users but also points for the user profile completeness and identity verifications from Trufina. Each rating is qualitative and focused on the

5. http://www.igotspam.com/50226711/naymz_sending_spamas_you.php accessed on the 16th of July 2008.

professional contexts of the target user ("Would you like to work on a team with the user)? The answers can be changed at any time. Only users who are part of the target user list of contacts are allowed to rate the user. There is no specific transaction-based rating, for example, for an e-commerce transaction.

- Monitoring, Analysis and Warnings: Naymz has many monitoring features for both inside and outside Naymz reputation evidence. There is a free list of Web sources (Web sites, forum, blogs...) that have mentioned the user's name. A premium monitoring tool allows the user to see on a worldwide map who has accessed the user Naymz profile including the visitor's IP address. It is possible to subscribe to other profiles recent Web activities if they are part of the user's confirmed contacts.
- Influencing, Promotion and Rewards: In addition to the RepScore and Web badges, the users can get ranking in Web search engines for a fee or for free if they maintain a RepScore higher than 9. The users can also get other features for free if they maintain a certain level of RepScore, for example, free detailed monitoring above 10. For a fee of 1 995 $ at time of writing, they also propose to shoot and produce high-quality, professional videos, to improve the user "personal brand".
- Interaction Facilitation and Follow-up: It is possible to search for users based on keywords but the search options and index are not advanced at time of writing.
- Reputation Certification and Assurance: As said above, Trufina is in charge of certifying identity and background user information.
- Fraud Protection, Mediation, Cleaning and Recovery: There are links to report offensive or defaming information to the support employees. The attack-resistance of the RepScore cannot be assessed because the algorithm detail is not public. They have also launched a new service called "Naymz Reputation Repair" whereby a user can indicate the location of external Web pages that contain embarrassing information as well as some information regarding the issues and after analysis Naymz may offer to take actions to remove the embarrassing information for a fee.

The GORB

Founded in 2006, The GORB [35] allowed anybody to rate any email address anonymously. At time of writing the second edition of this book chapter, this service has also been closed, apparently also due to a failing business model. The users could create an account to be allowed to display their GORB score with a Web badge and be notified of their and others reputation evolution. The GORB was very strict regarding their rule of anonymity: the users were not allowed to know who had rated them. The GORB addressed the different reputation service categories as follows:

- Reputation Calculation: They argue that, although they only use anonymous ratings, their reputation algorithm is attack-resistant but it is impossible to assess because it is not public. Apparently, they allow a user to rate several times another email address but they warn that multiple ratings may decrease the GORB score of the rater. The rating has two contexts on a 0 to 10 scale: personal and professional. Keywords called tags can be added to the rating as well as a textual comment.
- Monitoring, Analysis and Warnings: The users can be notified by email when their reputation evolves or when the reputation of user-defined email addresses evolve. However, it does not monitor evidence outside the GORB.
- Influencing, Promotion and Rewards: A Web browser plug-in can be installed to visualize the reputation of email addresses appearing on Web pages in the Web browser. There is a ranking of the users based on the GORB score.
- Interaction Facilitation and Follow-up: There is no follow-up because the ratings are anonymous.
- Reputation Certification and Assurance: There is no feature in this category.
- Fraud Protection, Mediation, Cleaning and Recovery: The GORB does not allow the users to remove their email address from their list of emails. The GORB asks for users passwords to import email addresses from the list of contacts of other Web sites. Thus, one may argue that the GORB, even if the ratings are anonymous, is not very privacy-friendly.

ReputationDefender: Reputation.com

Founded in 2006, ReputationDefender [36] had the following products at time of this writing, during the first version of this book chapter:

- MyReputation and MyPrivacy, that crawl the Web to find reputation information about the users for 9,95 $ a month and allow them to ask for the deletion of embarrassing information for 29,95 $ per item;
- MyChild, which does the same as above, but for 9,95 $ a month and per child;
- MyEdge starting from 99$ to 499$ allows the user with the help of automated and professional copywriters to improve the online presence of a user, for example, in search engines such as Google and with third-person biographies written by professional copywriters.

At time of writing this second version of the book chapter, ReputationDefender has roughly still the same set of reputation services as listed above. It is still very aggressive regarding its marketing claims. Users who create an account have very few free services. The service sends them many "alarming" emails about new reputation threats that have been discovered. However, they can only see those threats if they subscribe to an upgraded account, which is not free. Between the first edition and the second edition of this book chapter, ReputationDefender has been able to acquire the reputation.com URL, which was not owned by them at time of writing the first version of the chapter. ReputationDefender has addressed the different reputation service categories as follows:

- Reputation Calculation: There is no feature in this category.
- Monitoring, Analysis and Warnings: As said above, the whole Web is crawled and synthetic online reports are provided.
- Influencing, Promotion and Rewards: The user reputation may be improved based on expert advices and better positioned in Web search engines.
- Interaction Facilitation and Follow-up: There is no feature in this category.
- Reputation Certification and Assurance: There is no feature in this category.
- Fraud Protection, Mediation, Cleaning and Recovery: There is no reputation algorithm. Cleaning may involve from automated software to real people specialized in legal reputation issues.

Klout

We have seen above different e-reputation calculation services that existed at time of writing the first version of this chapter and disappeared before the second version of this chapter is finalized. Klout [37] is a service that did not exist at time of writing the first version of this chapter. It was created in 2008 by Joé Fernandez in San Francisco when he was injured and could not speak. Klout, instead of computing the reputation of a person mainly based on recommendations from other users as we have seen above in previous reputation calculation services, analyses the Twitter account of that person. Klout score is based on 3 main criterions:

- True Reach: the number of followers of the user's Twitter account and following the user's tweets
- Amplification: the number of people who share a post (who distribute it to other users)
- Network: the influence of the users composing the True Reach themselves

Klout may integrate other evidence such as posts on other social networks (such as Facebook) or other users who recommend the user by adding a +K to the user on specific topics, meaning that they click on a link provided by Klout saying that the user has influenced them regarding that topic. There are similar metrics that have been created since Klout, for example, Twitalizer (which is a very detailed one focusing on Twitter information), Peerindex, Kred, Identified, PROSkore, Jitterater (acquired at time of writing by Meltwater [10])... Unfortunately most of those metrics are not open (it is not really clear how the results have been computed and based on which evidence). Klout initial business models is based on the fact that users with high Klout score in some topic would be rewarded by brands willing to influence that topic. For example, Virgin Airline gave free airline tickets to users with high Klout score. At time of writing the second version of this book chapter, it is still not possible to reward users outside the USA and its business model has still to prove its viability. Anyway, Klout has gained a decent level of visibility compared to earlier e-reputation calculation services, maybe because many more users use social networks than before and e-reputation has become a hot product in traditional marketing companies. Klout has addressed the different reputation service categories as follows:

- Reputation Calculation: Klout calculates a score for the user, mainly based on Twitters performance but information from other social networks is also taken into account.
- Monitoring, Analysis and Warnings: Once the Klout account is linked to a user's social network, it can detect automatically when the user sends a new post and check how much buzz it has generated. If another user gives the user a +K, she is informed by email or a notification on her social networks.
- Influencing, Promotion and Rewards: The Klout users with higher scores may be rewarded by brands willing to influence its network through those users. The Klout rewards are called "perks".
- Interaction Facilitation and Follow-up: Although Klout provides a Web interface and widgets showing the user's Klout score, there is no secure check of the information provided by another user concerning an interaction besides the fact that she can specify that she has been influenced by giving a +K in a specific topic.
- Reputation Certification and Assurance: There is no feature in this category.
- Fraud Protection, Mediation, Cleaning and Recovery: There is no feature in this category, especially because Klout focuses on positive interactions, meaning that it is possible to say that another user has influenced the

current user but not that she has been betrayed by this other user.

e-Reputation Monitoring Services

Since the first version of this book chapter, several online reputation monitoring services have been created. Those services do not focus on computing the reputation score of a specific entity based on transactions but continuously analyse the online posts about the entity and warn this entity if some posts may decrease their reputation. In order to facilitate reacting in case of a potentially harmful post (by commenting on this post, most of these services provide a "engagement" web-based interface where posts authors, content and comments can be easily managed (stored, retrieved, commented, monitored...)). A few of these services allow for the monitoring of many entities based on archived content. However, the more entities and post can be retrieved, the more expensive the service is, at time of writing around several thousands of dollars per month. For example, Sysomos [38] products continuously crawls many sources (public Web sites, social networks, blogs...) and its MAP product allows the user to search for posts about an entity back to up to two years. Sysomos has also a cheaper service that focuses on only entity and provides "engagement" interfaces for this entity. The cheaper services do not give access to archives before the account is created for a specific search entity, e.g., the name of the company to be monitored. A few services argue to make automatic sentiment analysis of posts in different languages, such as Sysomos. Unfortunately most of these services automatic sentiment analysis feature only work well for English so far. A few of these services existed before the term "online reputation" gained popularity, for example, Digimind [39], which is originally a business intelligence service that has added e-reputation services such as engagement in 2012. Another older service that is specialized in newspapers monitoring called Meltwater added a social network influence score to its Meltwater Buzz product in 2012. The main e-reputation monitoring services are: Sysomos, Alterian SM2, Digimind e-reputation, Meltwater Buzz, Ubervu, Brandseye and TrendyBuzz.

e-Reputation Insurances

Although e-reputation insurances did not exist at time of writing the first version of this book chapter, traditional insurance companies have started selling online reputation insurance since June 2011. SwissLife was the first insurance company to propose an insurance to protect a person against e-reputation damages. Axa also proposes such an insurance. However those insurances are quite limited with regard to the e-reputation damages that they cover. The maximum amount that they guarantee against an online reputation damage is quite limited, up to around ten thousands Euros. They cost around 20 Euros per month. They guarantee to put in place means to mitigate the online reputation damage up to this maximum amount but they do not guarantee to fully recover from the online reputation damage. For example, they will cover the price of using an online reputation protection third-party service, which will try basic means to recover, e.g., creating positive well-referenced Web pages that appear first in Google search results before the Web pages with the reputation issues. Unfortunately, they will stop covering the fees of an external specialized online reputation lawyer as soon as the fees reach the maximum amount of money guaranteed by the insurance.

6. SUMMARY

Online reputation management is an emerging complementary field of computer security whose traditional security mechanisms are challenged by the openness of the World Wide Web where there is no a priori information of who is allowed to do what. There are still remaining technical issues to overcome: the attack-resistance of reputation algorithm is not mature yet; it is difficult to represent in a consistent way reputation built from different contexts (e-commerce, friendship...).

Sustainable business models are still to be found: Opinity seems to have run out of business; Rapleaf had to move from a reputation service to a privacy-risky business of email addresses marketing profiling; TrustPlus had to form an alliance with ZoomInfo, Xing and SageFire but eventually had to close its service in April 2012; the GORB has also had to close; Naymz decreased its own reputation by spamming its base of users in hope to increasing its traffic and has recently changed its name to visibleme.com; new services based on another type of calculation such as Klout have emerged but their business model has still to be confirmed over the next couple of years. Many online reputation monitoring services have also been started. Although their business model seems clearer, as older companies, strong in other domains such as Meltwater or Digimind, have created their own solutions, we might expect that a number of these services will have merged or disappeared in a few years time. Concerning e-reputation insurances services, traditional insurance companies have created them and therefore they are less prone to disappear than the online reputation services launched by startup companies with unproven business models.

It seems that both current technical and commercial issues may be improved by a standardization effort of online reputation management. The attack-resistance of reputation algorithms cannot be certified to the degree it

deserves if the reputation algorithms remain private. It has been proven in other security domains that security through obscurity gives lower results, for example, concerning cryptographic algorithms that are now open to review by the whole security research community. Open reputation algorithms will also improve the credibility of the reputation results because it will be possible to clearly explain to the users how the reputation has been calculated. The standardization of the representation of reputation will also diminish the confusion to the eyes of the users. The clearer understanding of which reputation evidence is taken into account in reputation calculation will improve the situation regarding privacy and will open the door for stronger regulation on how reputation information flows.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The state-of-the-art is clearly satisfactory, instead, mobile users and devices need the ability to autonomously authenticate and authorize other parties that they encounter on their way, without relying on a common authentication infrastructure.
2. True or False? The information on the outcomes of the present interactions with the trustee that are used for trust can come from different sources.
3. True or False? Trust engines, based on computational models of the human notion of trust, have been proposed to make security decisions on behalf of their owner.
4. True or False? In most commercial reputation services suveyed, the reputation calculation does take into account the attack-resistance of their algorithm.
5. True or False? Most of the current online reputation services surveyed do really compute reputation.

Multiple Choice

1. What is computed based on transactions that are quite well tracked, which is important to avoid faked evidence?
   A. Reputation
   B. Vulnerabilities
   C. Log
   D. Encrypted
   E. DHS
2. What has been one of the first commercial effort to build decentralized online reputation for users in all contexts beyond eBay's limited e-commerce context?
   A. Opinity
   B. Risk assessment
   C. Scale
   D. Access
   E. Active monitoring
3. What is the first built reputation about email addresses?
   A. Organizations
   B. Rapleaf
   C. Worms
   D. Logs
   E. Security
4. What provided a worldwide people reputation index, called the Vindex, based on either direct ratings through the user profile on Venyo Web site or indirect ratings through contributions or profiles on partner Web sites?
   A. Organizations
   B. Denial of service attack
   C. Venyo
   D. Port traffic
   E. Taps
5. What is another decentralized e-reputation calculation service?
   A. Systems security plan
   B. TrustPlus
   C. Denying service
   D. Decision making
   E. Challenge-Handshake Authentication Protocol (CHAP)

EXERCISE

Problem

Can online e-Reputation management services solve problems overnight?

Hands-On Projects

Project

Can online e-Reputation management services make negative results disappear forever?

Case Projects

Problem

What is a web e-Reputation service?

Optional Team Case Project

Problem

What are the levels that determine if an access to a URL will be blocked or allowed?

Chapter 66

Content Filtering

Pete Nicoletti, CISSP, CISA, CCSK
Director of Security Solutions and Compliance at Virtustream, Inc.

Note: This chapter is available in its entirety online at store.elsevier.com/product.jsp?isbn=9780123943972 (click the Resources tab at the bottom of the page).

1. ABSTRACT

Content filtering is a powerful tool that, properly deployed, can offer parents, companies, and local, state, and federal governments protection by classifying Internet-based content. It is disparaged as Orwellian and simultaneously embraced as a positive ROI project, depending on who you are and how it affects your online behavior. In this chapter we examine the many benefits and justifications of Web-based content filtering, such as legal liability, risk reduction, productivity gains, and bandwidth usage. We'll explore the downside and unintended consequences and risks that improperly deployed or misconfigured systems create. We'll also look into methods to subvert and bypass these systems and the reasons behind them. It is important for people who are considering content filtering to be aware of all the legal implications, and we'll also review these. Content filtering is straightforward to deploy, and license costs are so reasonable they can offer extremely fast return on investment while providing a very effective risk reduction strategy. We'll make sure that your project turns out successfully, since we'll look at all the angles: Executives will be happy with the project results and employees won't key your car in the parking lot!

2. CONTENTS

1. **Defining the Problem**
2. **Why Content Filtering Is Important**
   - Schools
   - Why Content Filtering Is Important
   - Financial Organizations
   - Healthcare Organizations
   - Internet Service Providers
   - U.S. Government
   - Other Governments
   - Libraries
   - Parents
3. **Content Categorization Technologies**
   - Keyword Lists
   - URL Lists
   - Content Categorization as a Service
   - Bayesian Filters
   - Content Labeling
   - Content-Based Image Filtering (CBIF)
4. **Perimeter Hardware And Software Solutions**
   - Proxy Server vs. Firewall
   - Internet Gateway-Based Products/Unified Threat Appliances
5. **Categories**
6. **Legal Issues**
   - Federal Law: ECPA
   - CIPA: The Children's Internet Protection Act
   - The Trump Card of Content Filtering: The "National Security Letter"
7. **Circumventing Content Filtering**
   - Circumvention Technologies
   - Proxies
   - Client-Based Proxies and Tunneling
   - Open "Explicit" Proxies
   - HTTP Web-Based Proxies (Public and Private)
   - Secure Public Web-Based Proxies
   - Process Killing
   - Remote PC Control Applications
8. **Additional Items To Consider: Overblocking and Underblocking**
   - Casual Surfing Mistake
   - Getting the List Updated
   - Override Authorization Methods
   - Warn and Allow Methods
   - Integration with Spam Filtering tools
   - Spyware and Malware Categories
   - Integration with Directory Servers

Data Loss Protection

Ken Perkins
Blazent Incorporated

IT professionals are tasked with the some of the most complex and daunting tasks in any organization. Some of the roles and responsibilities are paramount to the company's livelihood and profitability and maybe even the ultimate survival of the organization. Some of the most challenging issues facing IT professionals today are securing communications and complying with the vast number of data privacy regulations. Secure communications must protect the organization against spam, viruses, and worms; securing outbound traffic; guaranteeing the availability and continuity of the core business systems (such as corporate email, Internet connectivity, and phone systems), all while facing an increasing workload with the same workforce. In addition, many organizations face challenges in meeting compliance goals, contingency plans for disasters, detecting and/or preventing data misappropriation, and dealing with hacking, both internally and externally.

Almost every week, IT professionals can open the newspaper or browse online news sites and read stories that would keep most people up at night (see sidebar, "Stealing Trade Secrets From E. I. du Pont de Nemours and Company"). The dollar amounts lost are staggering and growing each year (see sidebar, "Stored Secure Information Intrusions"). Pressures of compliance regulations, brand protection, and corporate intellectual property are all driving organizations to evaluate and/or adopt data loss protection (DLP) solutions.

Stealing Trade Secrets from E. I. du Pont de Nemours and Company

WILMINGTON, DE—Colm F. Connolly, United States Attorney for the District of Delaware; William D. Chase, Special Agent in Charge of the Baltimore Federal Bureau of Investigation (FBI) Field Office; and Darryl W. Jackson, Assistant Secretary of Commerce for Export Enforcement, announced today the unsealing of a one-count Criminal Information charging Gary Min, a.k.a. Yonggang Min, with stealing trade secrets from E. I. du Pont de Nemours and Company ("DuPont"). Min pleaded guilty to the charge on November 13, 2006. The offense carries a maximum prison sentence of 10 years, a fine of up to $250,000, and restitution.

Pursuant to the terms of the plea agreement, Min admitted that he misappropriated DuPont's proprietary trade secrets without the company's consent and agreed to cooperate with the government.

According to facts recited by the government and acknowledged by Min at Min's guilty plea hearing, Min began working for DuPont as a research chemist in November 1995. Throughout his tenure at DuPont, Min's research focused generally on polyimides, a category of heat and chemical resistant polymers, and more specifically on high-performance films. Beginning in July 2005, Min began discussions with Victrex PLC about possible employment opportunities in Asia. Victrex manufactures PEEK,™ a polymer compound that is a functional competitor with two DuPont products, Vespel® and Kapton®. On October 18, 2005, Min signed an employment agreement with Victrex, with his employment set to begin in January 2006. Min did not tell DuPont that he had accepted a job with Victrex, however, until December 12, 2005.

Between August 2005 and December 12, 2005, Min accessed an unusually high volume of abstracts and full-text. pdf documents off of DuPont's Electronic Data Library ("EDL").The EDL server, which is located at DuPont's experimental station in Wilmington, is one of DuPont's primary databases for storing confidential and proprietary information. Min downloaded approximately 22,000 abstracts from the EDL and accessed approximately 16,706 documents—fifteen times the number of abstracts and reports accessed by the next highest user of the EDL for that period. The vast majority of Min's EDL searches were unrelated to his research responsibilities and his work on high-performance films. Rather, Min's EDL searches covered most of DuPont's major technologies and product lines, as well as new and emerging technologies in the research and development stage. The fair market value of the technology accessed by Min exceeded $400 million.

After Min gave DuPont notice that he was resigning to take a position at Victrex, DuPont uncovered Min's

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00067-2

unusually-high EDL usage. DuPont immediately contacted the FBI in Wilmington, which launched a joint investigation with the United States Attorney's Office and the United States Department of Commerce. Min began working at Victrex on January 1, 2006. On or about February 2, 2006, Min uploaded approximately 180 DuPont documents—including documents containing confidential, trade secret information—to his Victrex-assigned laptop computer. On February 3, 2006, DuPont officials told Victrex officials in London about Min's EDL activities and explained that Min had accessed confidential and proprietary action. Victrex officials seized Min's laptop computer from him on February 8, 2006, and subsequently turned it over to the FBI."[1]

Stored Secure Information Intrusions

Retailer TJX suffered an unauthorized intrusion or intrusions into portions of its computer system that process and store information related to credit and debit card, check and unreceipted merchandise return transactions (the intrusion or intrusions, collectively, the "Computer Intrusion"), which was discovered during the fourth quarter of fiscal 2007. The theft of customer data primarily related to portions of the transactions at its stores (other than Bob's Stores) during the periods 2003 through June 2004 and mid-May 2006 through mid-December 2006.

During the first six months of fiscal 2007 TJX incurred pretax costs of $38 million for costs related to the Computer Intrusion. In addition, in the second quarter ended July 28, 2007, TJX established a pretax reserve for its estimated exposure to potential losses related to the Computer Intrusion and recorded a pretax charge of $178 million. As of January 26, 2008, TJX reduced the reserve by $19 million, primarily due to insurance proceeds with respect to the Computer Intrusion, which had not previously been reflected in the reserve, as well as a reduction in estimated legal and other fees as the Company has continued to resolve outstanding disputes, litigation, and investigations. This reserve reflects the Company's current estimation of probable losses in accordance with generally accepted accounting principles with respect to the Computer Intrusion and includes a current estimation of total potential cash liabilities from pending litigation, proceedings, investigations and other claims, as well as legal and other costs and expenses, arising from the Computer Intrusion. This reduction in the reserve results in a credit to the Provision for Computer Intrusion related costs of $19 million in the fiscal 2007 fourth quarter and a pretax charge of $197 million for the fiscal year ended January 26, 2008.

The Provision for Computer Intrusion related costs increased fiscal 2008 fourth quarter net income by $11 million, or $0.02 per share, and reduced net income from continuing operations for the full fiscal 2008 year by $119 million, or $0.25 per share.[2]

Note: In the June 2007 General Accounting Office article, "GAO-07-737 Personal Information: Data Breaches Are Frequent, But Evidence of Resulting Identity Theft Is Limited; However, the Full Extent Is Unknown," 31 companies that responded to a 2006 survey said they incurred an average of $1.4 million per data breach.[3]

1. PRECURSORS OF DLP

Even before the Internet and all the wonderful benefits it brings to the world, organizations' data were exposed to the outside world. Modems, telex, and fax machines were some of the first enablers of electronic communications. Electronic methods of communications, by default, increase the speed and ease of communication, but they also create inherent security risks. Once IT organizations noticed they were at risk, they immediately started focusing on creating impenetrable moats to surround the "IT castle." As communication protocols standardized and with the mainstream adoption of the Internet, Transmission Control Protocol/Internet Protocol (TCP/IP) became the generally accepted default language of the Internet. This phenomenon brought to light external-facing security technologies and consequently their quick adoption. Some common technologies that protect TCP/IP networks from external threats are:

- *Firewalls.* Inspect network traffic passing through it, and denies or permits passage based on a set of rules.
- *Intrusion detection systems (IDSs).* Sensors log potential suspicious activity and allow for the remediation of the issue.
- *Intrusion prevention systems (IPSs).* React to suspicious activity by automatically performing a reset to the connection or by adjusting the firewall to block network traffic from the suspected malicious source.
- *Antivirus protection.* Attempts to identify, neutralize, or eliminate malicious software.
- *Antispam technology.* Attempts to let in "good" emails and keep out "bad" emails.

The common thread in these technologies: Keep the "bad guys" out while letting normal, efficient business processes occur. These technologies initially offered some very high-level, nongranular features such as blocking a TCP/IP port, allowing communications to and from a certain range of IP addresses, identifying keywords (without context or much flexibility), signatures of

1. "Guilty plea in trade secrets case," Department of Justice Press Release, February 15, 2007.

2. "SEC EDGAR filing information form 8-K," TJX Companies, Inc., February 20, 2008.

3. "GAO-07-737 personal information: Data breaches are frequent, but evidence of resulting identity theft is limited; however, the full extent is unknown," General Accounting Office, June 2007.

viruses, and blocking spam that used common techniques used by spammers.

Once IT organizations had a good handle on external-facing services, the next logical thought comes to mind: What happens if the "bad guy," undertrained or undereducated users, already have access to the information contained in an organization? In some circles of IT, this animal is simply known as an employee. Employees, by their default, "inside" nature, have permission to access the company's most sensitive information to accomplish their jobs. Even though the behavior of nonmalicious employees might cause as much damage as an intentional act, the disgruntled employee or insider is a unique threat that needs to be addressed.

The disgruntled insider, working from within an organization, is a principal source of computer crimes. Insiders may not need a great deal of knowledge about computer hacking because their knowledge of a victim's system often allows them to gain unrestricted access to cause damage to the system or to steal system data. With the advent of technology outsourcing, even non-employees have the rights to view/create/delete some of the most sensitive data assets within an organization. The insider threat could also include contractor personnel and even vendors working onsite. To make matters worse, the ease of finding information to help with hacking systems is no harder than typing a search string into popular search engines. The following is an example of how easy it is for non-"black hats" to perform complicated hacks without much technical knowledge:

1. Open a browser that is connected to the Internet.
2. Go to any popular Internet search engine site.
3. Search for the string "cracking WEP How to."

Note: Observe the number of articles, most with step-by-step instructions, on how to find the Wired Equivalent Privacy (WEP) encryption key to "hijack" a Wi-Fi access point.

So, what happens if an inside worker puts the organization at risk through his activity on the network or corporate assets? The next wave of technologies that IT organizations started to address dealt with the "inside man" issue. Some examples of these types of technologies include:

- *Web filtering.* Can allow/deny content to a user, especially when it is used to restrict material delivered over the Web.
- *Proxy servers.* Services the requests of its clients by forwarding requests to other servers and may block entire functionality such as Internet messaging/chat, Web email, and peer-to-peer file sharing programs.
- *Audit systems (both manual and automated).* Technology that records every packet of data that enters/leave the organization's network. Can be thought of as a network "VCR." Automated appliances feature post-event investigative reports. Manual systems might just use open-source packet-capture technologies writing to a disk for a record of network events.
- *Computer forensic systems.* Is a branch of forensic science pertaining to legal evidence found in computers and digital storage media. Computer forensics adheres to standards of evidence admissible in a court of law. Computer forensics experts investigate data storage devices (such as hard drives, USB drives, CD-ROMs, floppy disks, tape drives, etc.), identifying, preserving, and then analyzing sources of documentary or other digital evidence.
- *Data stores* for email governance.
- *IM- and chat-monitoring services.* The adoption of IM across corporate networks outside the control of IT organizations creates risks and liabilities for companies who do not effectively manage and support IM use. Companies implement specialized IM archiving and security products and services to mitigate these risks and provide safe, secure, productive instant-messaging capabilities to their employees.
- *Document management systems.* A computer system (or set of computer programs) used to track and store electronic documents and/or images of paper documents.

Each of these technologies are necessary security measures implemented in [or "by"] IT organizations to address point or niche areas of vulnerabilities in corporate networks and computer assets.

Even before DLP became a concept, IT organizations have been practicing the tenets of DLP for years. Firewalls at the edge of corporate networks can block access to IP addresses, subnets, and Internet sites. One could say this is the first attempt to keep data where it should reside, within the organization. DLP should be looked at nothing more than the natural progression of the IT security life cycle.

2. WHAT IS DLP?

Data loss protection is a term that has percolated up from the alphabet soup of computer security concepts in the past few years. Known in the past as information leak detection and prevention (ILDP), used by IDC; information protection and control (IPC); information leak prevention (ILP), coined by Forrester; content monitoring and filtering (CMF), suggested by Gartner; or extrusion prevention system (EPS), the opposite of intrusion prevention system (IPS), the acronym DLP seems to have won out. No matter what acronym of the day is used,

DLP is an automated system to identify anything that leaves the organization that could harm the organization.

DLP applications try to move away from the point or niche application and give a more holistic approach to coverage, remediation and reporting of data issues. One way of evaluating an organization's level of risk is to look around in an unbiased fashion. The most benign communication technologies could be used against the organization and cause harm.

Before embarking on a DLP project, understanding some example types of harm and/or the corresponding regulations can help with the evaluation. The following sidebar, "Current Data Privacy Legislation and Standards," addresses only a fraction of current data privacy legislation and standards but should give the reader a good understanding of the complexities involved in protecting data.

Current Data Privacy Legislation and Standards

Examples of Harm

Scenario

An administrative assistant confirms a hotel reservation for an upcoming conference by emailing a spreadsheet with employee's credit card numbers with expiration dates; sometimes if they want to make it really easy for the "bad guys," an admin will include the credit card's "secret" PIN, also known as card verification number (CVN).

Problem

Possible violation of GLBA and puts the organization's employees at risk for identity theft and credit card fraud.

Legislation

Gramm-Leach-Bliley Act

GLBA compliance is mandatory; whether a financial institution discloses nonpublic information or not, there must be a policy in place to protect the information from foreseeable threats in security and data integrity.

Major components put into place to govern the collection, disclosure, and protection of consumers' nonpublic personal information; or personally identifiable information:

- Financial Privacy Rule
- Safeguards Rule
- Pretexting Protection

Financial Privacy Rule

(Subtitle A: Disclosure of Nonpublic Personal Information, codified at 15 U.S.C. § 6801–6809)

The Financial Privacy Rule requires financial institutions to provide each consumer with a privacy notice at the time the consumer relationship is established and annually thereafter. The privacy notice must explain the information collected about the consumer, where that information is shared, how that information is used, and how that information is protected. The notice must also identify the consumer's right to opt out of the information being shared with unaffiliated parties per the Fair Credit Reporting Act. Should the privacy policy change at any point in time, the consumer must be notified again for acceptance. Each time the privacy notice is reestablished, the consumer has the right to opt-out again. The unaffiliated parties receiving the nonpublic information are held to the acceptance terms of the consumer under the original relationship agreement. In summary, the financial privacy rule provides for a privacy policy agreement between the company and the consumer pertaining to the protection of the consumer's personal nonpublic information.

Safeguards Rule

(Subtitle A: Disclosure of Nonpublic Personal Information, codified at 15 U.S.C. § 6801–6809)

The Safeguards Rule requires financial institutions to develop a written information security plan that describes how the company is prepared for and plans to continue to protect clients' nonpublic personal information. (The Safeguards Rule also applies to information of those no longer consumers of the financial institution.) This plan must include:

- Denoting at least one employee to manage the safeguards
- Constructing a thorough risk management on each department handling the nonpublic information
- Developing, monitoring, and testing a program to secure the information
- Changing the safeguards as needed with the changes in how information is collected, stored, and used

This rule is intended to do what most businesses should already be doing: *protect their clients*. The Safeguards Rule forces financial institutions to take a closer look at how they manage private data and to do a risk analysis on their current processes. No process is perfect, so this has meant that every financial institution has had to make some effort to comply with the GLBA.

Pretexting Protection

(Subtitle B: Fraudulent Access to Financial Information, codified at 15 U.S.C. § 6821–6827)

Pretexting (sometimes referred to as *social engineering*) occurs when someone tries to gain access to personal nonpublic information without proper authority to do so. This may entail requesting private information while impersonating the account holder, by phone, by mail, by email, or even by phishing (i.e., using a phony Web site or email to collect data). The GLBA encourages the organizations covered by the GLBA to implement safeguards against pretexting. For example, a well-written plan to meet GLBA's Safeguards Rule ("develop, monitor, and test a program to secure the information") ought to include a section on training employees to recognize and deflect inquiries made under pretext. In the United States, pretexting by individuals is punishable as a common law crime of False Pretenses.

Scenario

An HR employee, whose main job function is to process claims, forwards via email an employee's Explanation of

Benefits that contains a variety of Protected Health Information. The email is sent in the clear, unencrypted, to the organization's healthcare provider.

Problem

Could violate the Health Insurance Portability and Accountability Act (HIPAA), depending on the type of organization.

Legislation

The Privacy Rule

The Privacy Rule took effect on April 14, 2003, with a one-year extension for certain "small plans." It establishes regulations for the use and disclosure of Protected Health Information (PHI). PHI is any information about health status, provision of health care, or payment for health care that can be linked to an individual. This is interpreted rather broadly and includes any part of a patient's medical record or payment history.

Covered entities must disclose PHI to the individual within 30 days upon request. They also must disclose PHI when required to do so by law, such as reporting suspected child abuse to state child welfare agencies.

A covered entity may disclose PHI to facilitate treatment, payment, or healthcare operations or if the covered entity has obtained authorization from the individual. However, when a covered entity discloses any PHI, it must make a reasonable effort to disclose only the minimum necessary information required to achieve its purpose.

The Privacy Rule gives individuals the right to request that a covered entity correct any inaccurate PHI. It also requires covered entities to take reasonable steps to ensure the confidentiality of communications with individuals. For example, an individual can ask to be called at his or her work number, instead of home or cell phone number.

The Privacy Rule requires covered entities to notify individuals of uses of their PHI. Covered entities must also keep track of disclosures of PHI and document privacy policies and procedures. They must appoint a Privacy Official and a contact person responsible for receiving complaints and train all members of their workforce in procedures regarding PHI.

An individual who believes that the Privacy Rule is not being upheld can file a complaint with the Department of Health and Human Services Office for Civil Rights (OCR).

Scenario

An employee opens an email whose subject is "25 Reasons Why Beer is Better than Women." The employee finds this joke amusing and forwards the email to other coworkers using the corporate email system.

Problem

Puts the organization in an exposed position for claims of sexual harassment and a hostile workplace environment.

Legislation

In the U.S., the Civil Rights Act of 1964 Title VII prohibits employment discrimination based on race, sex, color, national origin, or religion. The prohibition of sex discrimination covers both females and males. This discrimination occurs when the sex of the worker is made a condition of employment (i.e., all female waitpersons or male carpenters) or where this is a job requirement that does not mention sex but ends up barring many more persons of one sex than the other from the job (such as height and weight limits).

In 1998, Chevron settled, out of court, a lawsuit brought by several female employees after the "25 Reasons" email was widely circulated throughout the organization. Ultimately, Chevron settled out of court for $2.2 million.

Scenario

A retail store server electronically transmits daily point-of-sale (POS) transactions to the main corporate billing server. The POS system records the time, date, register number, employee number, part number, quantity, and if paid for by credit card, the card number. This transaction occurs nightly as part of a batch job and is transmitted over the store's Wi-Fi network.

Problem

PCI DSS stands for Payment Card Industry Data Security Standard. It was developed by the major credit card companies as a guideline to help organizations that process card payments prevent credit-card fraud, cracking, and various other security vulnerabilities and threats. A company processing, storing, or transmitting payment card data must be PCI DSS compliant or risk losing its ability to process credit card payments and being audited and/or fined. Merchants and payment card service providers must validate their compliance periodically. This validation gets conducted by auditors (that is persons who are the PCI DSS Qualified Security Assessors, or QSAs). Although individuals receive QSA status, reports on compliance can only be signed off by an individual QSA on behalf of a PCI council-approved consultancy. Smaller companies, processing *fewer* than about 80,000 transactions a year, are allowed to perform a self-assessment questionnaire. Penalties are often accessed and fines of $25,000 per month are possible for large merchants for noncompliance.

PCI DSS requires 12 requirements to be in compliance:

Requirement 1: Install and maintain a firewall configuration to protect cardholder data

Firewalls are computer devices that control computer traffic allowed into and out of a company's network, as well as traffic into more sensitive areas within a company's internal network. A firewall examines all network traffic and blocks those transmissions that do not meet the specified security criteria.

Requirement 2: Do not use vendor-supplied defaults for system passwords and other security parameters

Hackers (external and internal to a company) often use vendor default passwords and other vendor default settings to compromise systems. These passwords and settings are well known in hacker communities and easily determined via public information.

Requirement 3: Protect stored cardholder data

Encryption is a critical component of cardholder data protection. If an intruder circumvents other network security controls and gains access to encrypted data, without the proper cryptographic keys, the data is unreadable and unusable to that person. Other effective methods of protecting stored data should be considered as potential risk mitigation opportunities. For example, methods for minimizing risk include not storing cardholder data unless absolutely necessary,

truncating cardholder data if full PAN is not needed and not sending PAN in unencrypted emails.

Requirement 4: Encrypt transmission of cardholder data across open, public networks

Sensitive information must be encrypted during transmission over networks that are easy and common for a hacker to intercept, modify, and divert data while in transit.

Requirement 5: Use and regularly update anti-virus software or programs

Many vulnerabilities and malicious viruses enter the network via employees' email activities. Antivirus software must be used on all systems commonly affected by viruses to protect systems from malicious software.

Requirement 6: Develop and maintain secure systems and applications

Unscrupulous individuals use security vulnerabilities to gain privileged access to systems. Many of these vulnerabilities are fixed by vendor-provided security patches. All systems must have the most recently released, appropriate software patches to protect against exploitation by employees, external hackers, and viruses. *Note:* Appropriate software patches are those patches that have been evaluated and tested sufficiently to determine that the patches do not conflict with existing security configurations. For in-house developed applications, numerous vulnerabilities can be avoided by using standard system development processes and secure coding techniques.

Requirement 7: Restrict access to cardholder data by business need-to-know

This requirement ensures critical data can only be accessed by authorized personnel.

Requirement 8: Assign a unique ID to each person with computer access

Assigning a unique identification (ID) to each person with access ensures that actions taken on critical data and systems are performed by, and can be traced to, known and authorized users.

Requirement 9: Restrict physical access to cardholder data

Any physical access to data or systems that house cardholder data provides the opportunity for individuals to access devices or data and to remove systems or hardcopies, and should be appropriately restricted.

Requirement 10: Track and monitor all access to network resources and cardholder data

Logging mechanisms and the ability to track user activities are critical. The presence of logs in all environments allows thorough tracking and analysis if something does go wrong. Determining the cause of a compromise is very difficult without system activity logs.

Requirement 11: Regularly test security systems and processes

Vulnerabilities are being discovered continually by hackers and researchers, and being introduced by new software. Systems, processes, and custom software should be tested frequently to ensure security is maintained over time and with any changes in software.

Requirement 12: Maintain a policy that addresses information security for employees and contractors

A strong security policy sets the security tone for the whole company and informs employees what is expected of them. All employees should be aware of the sensitivity of data and their responsibilities for protecting it.[4]

Organizations are facing pressures to become Sarbanes-Oxley compliant.

SOX Section 404: Assessment of internal control

The most contentious aspect of SOX is Section 404, which requires management and the external auditor to report on the adequacy of the company's internal control over financial reporting (ICFR). This is the most costly aspect of the legislation for companies to implement, as documenting and testing important financial manual and automated controls requires enormous effort.

Under Section 404 of the Act, management is required to produce an "internal control report" as part of each annual Exchange Act report. The report must affirm "the responsibility of management for establishing and maintaining an adequate internal control structure and procedures for financial reporting." The report must also "contain an assessment, as of the end of the most recent fiscal year of the Company, of the effectiveness of the internal control structure and procedures of the issuer for financial reporting." To do this, managers are generally adopting an internal control framework such as that described in Committee of Sponsoring Organization of the Treadway Commission (COSO).

Both management and the external auditor are responsible for performing their assessment in the context of a top-down risk assessment, which requires management to base both the scope of its assessment and evidence gathered on risk. Both the Public Company Accounting Oversight Board (PCAOB) and SEC recently issued guidance on this topic to help alleviate the significant costs of compliance and better focus the assessment on the most critical risk areas.

The recently released Auditing Standard No. 5 of the PCAOB, which superseded Auditing Standard No 2. has the following key requirements for the external auditor:

- Assess both the design and operating effectiveness of selected internal controls related to significant accounts and relevant assertions, in the context of material misstatement risks
- Understand the flow of transactions, including IT aspects, sufficiently to identify points at which a misstatement could arise

For questions regarding the PCI Materials, please contact PCI SSC through its Web site at https://www.pcisecuritystandards.org."

- Evaluate company-level (entity-level) controls, which correspond to the components of the COSO framework
- Perform a fraud risk assessment
- Evaluate controls designed to prevent or detect fraud, including management override of controls
- Evaluate controls over the period-end financial reporting process;
- Scale the assessment based on the size and complexity of the company
- Rely on management's work based on factors such as competency, objectivity, and risk
- Evaluate controls over the safeguarding of assets
- Conclude on the adequacy of internal control over financial reporting

The recently released SEC guidance is generally consistent with the PCAOB's guidance above, only intended for management.

After the release of this guidance, the SEC required smaller public companies to comply with SOX Section 404, companies with year ends after December 15, 2007. Smaller public companies performing their first management assessment under Sarbanes-Oxley Section 404 may find their first year of compliance after December 15, 2007 particularly challenging. To help unravel the maze of uncertainty, Lord & Benoit, a SOX compliance company, issued "10 Threats to Compliance for Smaller Companies" (www.section404.org/pdf/sox_404_10_threats_to_compliance_for_smaller_public_companies.pdf), which gathered historical evidence of material weaknesses from companies with revenues under $100 million. The research was compiled aggregating the results of 148 first-time companies with material weaknesses and revenues under $100 million. The following were the 10 leading material weaknesses in Lord & Benoit's study: accounting and disclosure controls, treasury, competency and training of accounting personnel, control environment, design of controls/lack of effective compensating controls, revenue recognition, financial closing process, inadequate account reconciliations, information technology and consolidations, mergers, intercompany accounts.

Scenario

A guidance counselor at a high school gets a request from a student's prospective college. The college asked for the student's transcripts. The guidance counselor sends the transcript over the schools email system unencrypted.

Problem

FERPA privacy concerns, depending on the age of the student.

Legislation

The Family Educational Rights and Privacy Act (FERPA) (20 U.S.C. § 1232g; 34 CFR Part 99) is a federal law that protects the privacy of student education records. The law applies to all schools that receive funds under an applicable program of the U.S. Department of Education.

FERPA gives parents certain rights with respect to their children's education records. These rights transfer to the student when he or she reaches the age of 18 or attends a school beyond the high school level. Students to whom the rights have transferred are "eligible students."

Parents or eligible students have the right to inspect and review the student's education records maintained by the school. Schools are not required to provide copies of records unless, for reasons such as great distance, it is impossible for parents or eligible students to review the records. Schools may charge a fee for copies.

Parents or eligible students have the right to request that a school correct records that they believe to be inaccurate or misleading. If the school decides not to amend the record, the parent or eligible student then has the right to a formal hearing. After the hearing, if the school still decides not to amend the record, the parent or eligible student has the right to place a statement with the record setting forth his or her view about the contested information.

Generally, schools must have written permission from the parent or eligible student in order to release any information from a student's education record. However, FERPA allows schools to disclose those records, without consent, to the following parties or under the following conditions (34 CFR § 99.31):

- School officials with legitimate educational interest
- Other schools to which a student is transferring
- Specified officials for audit or evaluation purposes
- Appropriate parties in connection with financial aid to a student
- Organizations conducting certain studies for or on behalf of the school
- Accrediting organizations
- To comply with a judicial order or lawfully issued subpoena
- Appropriate officials in cases of health and safety emergencies
- State and local authorities, within a juvenile justice system, pursuant to specific State law

Schools may disclose, without consent, "directory" information such as a student's name, address, telephone number, date and place of birth, honors and awards, and dates of attendance. However, schools must tell parents and eligible students about directory information and allow parents and eligible students a reasonable amount of time to request that the school not disclose directory information about them. Schools must notify parents and eligible students annually of their rights under FERPA. The actual means of notification (special letter, inclusion in a PTA bulletin, student handbook, or newspaper article) is left to the discretion of each school.

Scenario

Employee job hunting, posting resumes and trying to find another job while working. See Figure 67.1 for an example of a DLP system capturing the full content of a user going through the resignation process.

Problem

Loss of productivity for that employee.

Warning sign for a possible disgruntled employee.

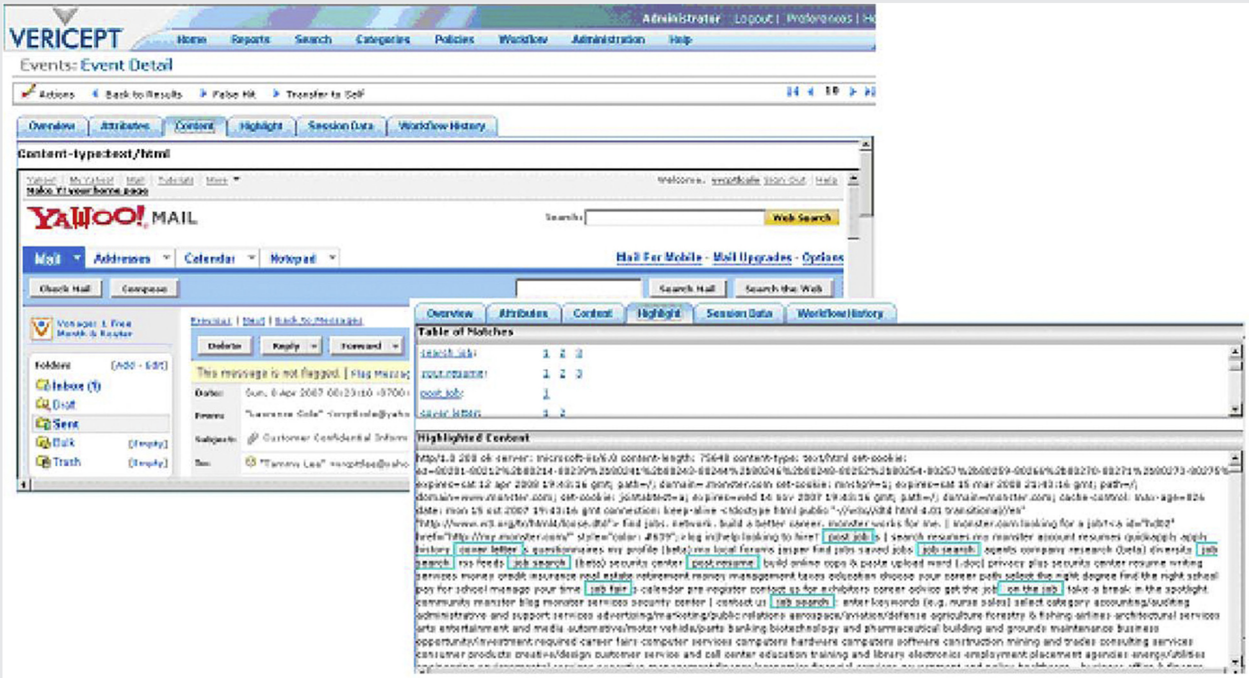

FIGURE 67.1 Webmail event: Content rendering of a resignation event.[5]

3. WHERE TO BEGIN?

A reasonable place to begin talking about DLP is with the department of the organization that handles corporate policy and/or governance (see sidebar, "An Example of an Acceptable Use Policy"). Monitoring employees is at best an interesting proposition. Corporate culture can drive whether monitoring of any kind is even allowed. A good litmus test would be the types of notice that appear in the employee handbook.

Another good indicator that the organization would be a good fit for a DLP application is the sign-on screen that appears before or after a computer user logs on to her workstation (see sidebar, "Accessing a Company's Information System").

Some organizations are more apt to take advantage of the laws and rights that companies have to defend themselves. Simply asking around and performing informal interviews with Human Resources, Security, and Legal can save days and weeks of time down the line.

In summary, implementing a DLP application without the proper Human Resources, Security, and Legal policies could be a waste of time because IT professionals *will* catch employees violating security standard. The events in a DLP system must be actionable and have "teeth" for changes to take place.

4. DATA IS LIKE WATER

As most anyone who has had a water leak in dwelling knows, water will find a way out of where it is supposed to go. Pipes are meant to direct the proper flow of water both in and out. If a leak happens, the occupant will eventually find a damp spot, a watermark, or a real drip. It might take minutes or days to notice the leak and might take just as long to find the source of the leak.

Much like the water analogy, employees are given data "pipes" to do their jobs with enabling technology provided by the IT organization. Instead of water flowing through, data can ingress/egress the organization in multiple methods.

Corporate email is a powerful efficient time saving tool that speeds communication. A user can attach a 10 megabyte file, personal pictures, a recipe for chili and next quarter's marketing plan or an acquisition target. Chat and IM is the quickest growing form of electronic communication and a great enabler of efficient workflow. Files can be sent as well over these protocols or "pipes." Web mail is usually the "weapon of choice" by users who like to conduct personal business at work. Web mail allows users to attach files of any type.

5. Figures 67.1, 67.2 (a–c) and 67.3 (a-b), inclusive of the Vericept trademark and logo, are provided by Vericept Corporation solely for use as screenshots herein and may not be reproduced or used in any other way without the prior written permission of Vericept Corporation. All rights reserved.

An Example of an Acceptable Use Policy

Use of Email and Computer Systems

All information created, accessed or stored using company applications, systems, or resources, including email, is the property of the company. Users do not have a right to privacy regarding any activity conducted using the company's system. The company can review, read, access, or otherwise monitor email and all activities on the company system or any other system accessed by use of the company system. In addition, the Company could be required to allow others to read email or other documents on the company's system in the context of a lawsuit or other legal action.

All users must abide by the rules of network etiquette, which include being polite and using the network and the Internet in a safe and legal manner. The company or authorized company officials will make a good faith judgment as to which materials, files, information, software, communications, and other content and activity are permitted and prohibited based on the following guidelines and under the particular circumstances.

Among the uses that are considered unacceptable and constitute a violation of this policy are the following:

- Using, transmitting, receiving, or seeking inappropriate, offensive, swearing, vulgar, profane, suggestive, obscene, abusive, harassing, belligerent, threatening, defamatory (harming another's reputation by lies), or misleading language or materials; revealing personal information such as another's home address, home telephone number, or Social Security number; making ethnic, sexual-preference, age or gender-related slurs or jokes.
- Users may never harass, intimidate, threaten others, or engage in other illegal activity (including pornography, terrorism, espionage, theft, or drugs) by email or other posting. All such instances should be reported to management for appropriate action. In addition to violating this policy, such behavior may also violate other company policies or civil or criminal laws.
- Among the uses that are considered unacceptable and constitute a violation of this policy are downloading or transmitting copyrighted materials without permission from the owner of the copyright on those materials. Even if materials on the network or the Internet are not marked with the copyright symbol, you should assume that they are protected under copyright laws unless there is explicit permission from the copyright holder on the materials to use them.
- Users must not use email or other communications methods, including but not limited to news group posting, blogs, forums, instant messaging, and chat servers, to send company proprietary or confidential information to any unauthorized party. Such information may be disclosed to authorized persons in encrypted files if sent over publicly accessible media such as the Internet or other broadcast media such as wireless communication. Such information may be sent in unencrypted files only within the company system. Users are responsible for properly labeling such information.

Certain specific policies extend the Company's acceptable use policy by placing further restrictions on that activity. Examples include, but are not limited to: software usage, network usage, shell policy, remote access policy, wireless policy, and the mobile email access policy. These and any additional policies are available from the IT Web site on the intranet.

Your use of the network and the Internet is a privilege, not a right. If you violate this policy, at a minimum you will be subject to having your access to the network and the Internet terminated. You breach this policy not only by affirmatively violating the above provisions but also by failing to report any violations of this policy by other users which come to your attention. Further, you violate this policy if you permit another to use your account or password to access the network or the Internet, including but not limited to someone whose access has been denied or terminated. Sharing your account with anyone is a violation of this policy. It is your responsibility to keep your account secure by choosing a sufficiently complex password and changing it on a regular basis.

Thus, the IT network "plumbing" needs to be monitored, maintained, and evaluated on an ongoing basis. The U.S. government has published a complete and well-rounded standard that organizations can use as a good first step to compare where they are strong and where they can use improvement.

The U.S. Government Federal Information Security Management Act of 2002 (FISMA) offers reasonable guidelines that most organizations could benefit by adopting. Even though FISMA is mandated for government agencies and contractors, it can be applied to the corporate world as well.

FISMA sets forth a comprehensive framework for ensuring the effectiveness of security controls over information resources that support federal operations and assets. FISMA's framework creates a cycle of risk management activities necessary for an effective security program, and these activities are similar to the principles noted in our study of the risk management activities of leading private sector organizations—assessing risk, establishing a central management focal point, implementing appropriate policies and procedures, promoting awareness, and monitoring and evaluating policy and control effectiveness. More specifically, FISMA requires the head of each agency to provide information security protections commensurate with the risk and magnitude of harm resulting from the unauthorized access, use, disclosure, disruption, modification, or destruction of information and information systems used or operated by the agency or on behalf of the agency. In this regard, FISMA

requires that agencies implement information security programs that, among other things, include:

- Periodic assessments of the risk
- Risk-based policies and procedures
- Subordinate plans for providing adequate information security for networks, facilities, and systems or groups of information systems, as appropriate
- Security awareness training for agency personnel, including contractors and other users of information systems that support the operations and assets of the agency
- Periodic testing and evaluation of the effectiveness of information security policies, procedures, and practices, performed with a frequency depending on risk, but no less than annually
- A process for planning, implementing, evaluating, and documenting remedial action to address any deficiencies
- Procedures for detecting, reporting, and responding to security incidents
- Plans and procedures to ensure continuity of operations

In addition, agencies must develop and maintain an inventory of major information systems that is updated at least annually and report annually to the Director of OMB and several Congressional Committees on the adequacy and effectiveness of their information security policies, procedures, and practices and compliance with the requirements of the act. An internal risk assessment of what types of "communication," both manual and electronic, that are allowed within the organization can give the DLP evaluator a baseline of the type of transmission that are probably taking place (see checklist: "An Agenda For Action For Evaluating Other Types Of Manual And Electronic Communications").

Accessing a Company's Information System

You are accessing a Company's information system (IS) that is provided for Company-authorized use only. By using this IS, you consent to the following conditions:

- The Company routinely monitors communications occurring on this IS, and any device attached to this IS, for purposes including, but not limited to, penetration testing, monitoring, network defense, quality control, and employee misconduct, law enforcement, and counterintelligence investigations.
- At any time the Company may inspect and/or seize data stored on this IS and any device attached to this IS.
- Communications occurring on or data stored on this IS, or any device attached to this IS, are not private. They are subject to routine monitoring and search.
- Any communications occurring on or data stored on this IS, or any device attached to this IS, may be disclosed or used for any Company-authorized purpose.
- Security protections may be utilized on this IS to protect certain interests that are important to the Company. For example, password, access cards, encryption or biométrie access controls provide security for the benefit of the Company. These protections are not provided for your benefit or privacy and may be modified or eliminated at the Company's discretion.

5. YOU DON'T KNOW WHAT YOU DON'T KNOW

Embarking on a DLP evaluation or implementation can be a straightforward exercise. The IT professional usually has a mandate in mind and a few problems that the DLP application will address. Invariably, many other issues will arise as DLP applications do a very good job at finding most potential security and privacy issues.

An Agenda for Action for Evaluating Other Types of Manual and Electronic Communications

Some types of communications that should be evaluated are not always obvious but could be just as damaging as electronic methods. The following list encompasses some of those obvious and not so obvious methods (Check All Tasks Completed):

_____**1.** Pencil and paper.
_____**2.** Photocopier.
_____**3.** Fax.
_____**4.** Voicemail.
_____**5.** Digital camera.
_____**6.** Jump drive.
_____**7.** MP3/iPod.
_____**8.** DVD/CD-ROM/3½ in. floppy.
_____**9.** Magnetic tape.
_____**10.** SATA drives.
_____**11.** IM/chat.
_____**12.** FTP/FTPS.
_____**13.** SMTP/POP3/IMAP.
_____**14.** HTTP post/response.
_____**15.** HTTPS.
_____**16.** Telnet.
_____**17.** SCP.
_____**18.** P2P
_____**19.** Rogue ports.
_____**20.** GoToMyPC.
_____**21.** Web conferencing systems.

Reports that say that something hasn't happened are always interesting to me, because as we know, there are 'known knowns'; there are things we know we know. We also know there are 'known unknowns'; that is to say we know there are some things we do not know. But there are also 'unknown unknowns '—the ones we don't know we don't know.

—Donald Rumsfeld, U.S. Department of Defense, February 12, 2002

Once the corporate culture has established that DLP is worth investigating or worth implementing, the next logical step would be performing a risk/exposure assessment. Several DLP vendors offer free pilots or proof of concepts and should be leveraged to jumpstart the data risk assessment for a very low monetary cost.

A risk/exposure assessment usually involves placing a server on the edge of the corporate network and sampling/recording the network traffic that is egressing the organization. In addition, the assessment might involve look for high-risk files at rest and the activity of what is happening on the workstation environment. Most if not all DLP applications have predefined risk categories that cover a wide range of risk profiles. Some examples are:

- Regulations: GLBA, HIPAA, PCI-DSS, SOX, FERPA, PHI
- Acceptable use: Violence, gangs, profanity, adult themes, weapons, harassment, racism, pornography
- Productivity: Streaming media, resignation, shopping, Webmail
- Insider hacker activity: Root activity, nmap, stack, smashing code, keyloggers

Deciding what risk categories are most important to your organization can streamline the DLP evaluation. If data categories are turned on but not likely to impact what is truly important to the organization, the test/pilot result will contain a lot of "noise." Focus on the "low-hanging fruit." For example, if the organization's life blood is customer data, focus on the categories that address those types of leaks.

Precision versus Recall

Before the precision versus recall discussion can take place, definitions are necessary:

- *False positive.* A false positive occurs when the DLP application-monitoring or DLP application-blocking techniques wrongly classify a legitimate transmission or event as "uninteresting" and, as a result, the event must be remediated anyway. Remediating an event is a time-consuming process which could involve one to many administrators dispositioning the event. A high number of false positives is normal during an initial implementation, but the number should fall after the DLP application is tuned.
- *False negative.* A false negative occurs when a transmission is not detected as interesting. The problem with false negatives is usually the DLP administrator does not know these transmissions are happening in the first place. An analogy would be a bank employee who embezzles thousands of dollars and the bank does not notice the theft until it is too late.
- *True positive.* Condition present and the DLP application records the event for remediation.
- *True negative.* Condition not present and the DLP application does not record it.

DLP application testing and tuning can involve a trade-off:

- The acceptable level of false positives (in which a nonmatch is declared to be a match).
- The acceptable level of false negatives (in which an actual match is not detected).

An evaluator can think of this process as a slider bar concept, with false negatives on the left side and false positives on the right. A properly tuned DLP application minimizes false positives and diminishes the chances of false negatives.

This iterative process of tuning is called *thresholding.* Creating the proper threshold eventually leads to the minimization of acceptable amounts of false positives with no or minimal false negatives.

An easy way to achieve thresholding is to make the test more restrictive or more sensitive. The more restrictive the test is, the higher the risk of rejecting true positives; and, the less sensitive the test is, the higher the risk of accepting false positives.

6. HOW DO DLP APPLICATIONS WORK?

The way that most DLP applications capture interesting events is through different kinds of analysis engines. Most support simple keyword matching. For example, any time you see the phrase "project phoenix" in a data transmission, the network event is stored for later review. Keywords can be grouped and joined. Regular expression (RegEx) support is featured in most of today's DLP applications. Regular expressions provide a concise and flexible means for identifying strings of text of interest, such as particular characters, words, or patterns of characters. Regular expressions are written in a formal language that can be interpreted by a regular expression processor, a program that either serves as a parser generator or examines text and identifies parts that match the provided specification. A real-world example would be the expression:

$$(r|b)?\text{ed}$$

Any transmission that contained the word *red, bed*, or even *ed* would be captured for later investigation. Regular expressions can also do pattern matching on credit card number and U.S. Social Security numbers:

$$\wedge \backslash d\{3\} - ?\backslash d\{2\} - ?\backslash d\{4\}$$

which can be read: Any three numbers followed by an optional dash followed by any two numbers followed by an optional dash and then followed by any four numbers. Regular expressions offer a certain level of efficiencies but cannot address all DLP concerns. Weighting of either keyword(s) and/or RegEx's can help. A real-world example might be the word *red* is worth three points and the SSN is worth five points, but for an event to hit the transmission, it must contain 22 points. In this example, four SSNs and the word *red* would trigger an event (4 times 5 plus 3 equals 23, which would trigger the event score rule). Scoring can help address the thresholding issue. To address some of the limitation of simple keyword and RegEx's, DLP applications can also look for data "signatures" or hashes of data. Hashing creates a mathematical representation of the sensitive data and looks for that signature. Sensitive data or representative types of data can be bulk loaded from databases and example files.

7. EAT YOUR VEGETABLES

DLP is like the layers of an onion. Once the first layer of protection is implemented, the next layer should/could be addressed. There are many different forms of DLP applications, depending on the velocity and location of the sensitive data.

Data in Motion

Data in motion is an easy place to start implementing a DLP application because most can function in "passive" mode, meaning it looks at only a copy of the actual data egressing/ingressing the network. One way to look at data-in-motion monitoring is like a very intelligent VCR. Instead of recording every packet of information that passes in and out of an organization, DLP applications only capture, flag, and record the transmissions that fall within the categories/policies that are turned on (see sidebar, "Case Study: DLP Applications"). There are two main types of data-in-motion analysis:

- *Passive monitoring*. Using a Switched Port Analyzer (SPAN) on a router, port mirror on a switch or a network tap(s) that feeds the outbound network traffic to the DLP application for analysis.
- Active (inline) enforcement. Using an active egress port or through a proxy server, some DLP applications can stop the transmission from happening. The port itself can be reset or the proxy server can show a failure of transmission. The event that keyed off the reset or failure is still recorded.

Case Study: DLP Applications

Background

A Fortune 500 Company has tens of thousands of employees with access to the Internet through an authenticated method. The Company has recently retired a version of laptops with the associated docking station, monitors and mice. New laptops were purchased and given to the employees. The old assets were retired to a storage closet. One manager noticed some docking stations had gone missing. That in and of itself was not concerning as this company had a liberal policy of donating old computer assets to charity. After looking in the company's Asset Management System and talking to the organization's charity manager, the manager found this was not the case. An investigation was launched both electronically and through traditional investigative means.

Action

The organization had a DLP application in use with data-in-motion implemented. This particular DLP application had a strong acceptable use set of categories/policies. One of them was "Shopping," which covered both traditional shopping outlets but also popular online auction sites. The DLP investigator selected the report that returns all transmissions that violated the "Shopping" category and contained the keyword of the model number of the docking station. Within seconds, a user from within their network was found auctioning the exact same model docking stations as the ones the company had just retired.

Result

The Fortune 500 Company was able to remediate a situation quickly that not only stopped the loss of physical assets, but get rid of an employee that was stealing while at work. The real value of this exercise could have been, if an employee is "ok" with stealing assets to make a few extra dollars on the company's dime, one might ask, What else might an employee that thinks it is ok to steal do?

Data at Rest

Static computer files on drives, removable media or even tape can grow to the millions in large multinational organizations. Unless tight controls are implemented, data can spawn out of control. Even though email transmissions account for more than 80% of DLP violations, data-at-rest files that are resting where they are not supposed to be can be a major concern (see sidebar, "Case Study: Data-at-Rest Files").

Data-at-rest risk can occur in other places besides the personal computer's file system. One of the benefits of

networked computer systems is the ability to share files. File shares can also pose a risk because the original owner of the file now has no idea what happened to the file after they share it.

The same can be said of many Web-based collaboration and document management platforms that are available in the market today. Collaboration tools can be used to host Web sites that can be used to access shared workspaces and documents, as well as specialized applications such as wikis, blogs, and many other forms of applications, from within a browser. Once again, the wonderful world of shared computing can also put an organization's data at risk.

DLP application can help with databases as well and half the battle is knowing where the organizations most sensitive data resides. The data-at-rest function of DLP applications can definitely help.

Data in Use

DLP applications can also help keep data where it is supposed to stay (see sidebar, "Case Study: Data-in-Use Files"). Agent-based technologies that run resident on the guest operating system can track, monitor, block, report, quarantine or notify the usage of particular kinds of data files and/or the contents of the file itself. Policies can be centrally administered and "pushed" out of the organization's computer assets. Since the agent is resident on the computer, it can also create an inventory of every file on the hard drives, removable media and even music players. Since the agent knows of the file systems down to the operating system level, it can allow or disallow certain types of removable media. For example, an organization might allow a USB storage device if and only if the device supports encryption. The agent will disallow any other types of USB devices such as music players, cameras, removable hard drives, and so on.

Case Study: Data-at-Rest Files

Background

A Fortune 500 Company has multiple customer service centers located throughout the United States. Each customer server representative has a personal computer with a hard drive and Internet access. The representative's job entails taking inbound phone calls to help their customers with account management including auto-pay features. Auto-pay setup information could include taking a credit-card number and expiration date and/or setting up an electronic fund transfer payment which includes an ABA routing number and account number. This sensitive information is supposed to be entered directly into the corporate enterprise resource planning (ERP) system application. Invariably customer service representatives run into issues during this process (connectivity to the ERP system is interrupted, power goes down, computer needs to be rebooted, etc.) and sensitive data finds its way into unapproved places on the personal computer—a note text file, a word-processing document, an electronic spreadsheet, or in an email system. Even though employees went through training for their job that included handling of sensitive data, the management suspected that data was finding a way out of the ERP system. Another issue that the management faced with a very high turnover ratio and that employee training was falling behind.

Action

A DLP data-at-rest pilot was performed and over one thousand files that contained credit-card numbers and other customer personal identifiable information were found.

Result

The Fortune 500 Company was able to cleanse the hard drives of files that contained sensitive data by using the legend the DLP application provided. More important, the systemic cause of the problem had to be readdressed with training and tightening down the security of the representative, personal computers.

Case Study: Data-in-Use Files

Background

An electronics manufacturer has created a revolutionary new design for a cell phone and wants to keep the design and photographs of the prototype under wraps. They have had problems in the past with pictures ending up on blog sites, competitors "borrowing" design ideas, and even other countries creating similar products and launching an imitator within weeks of the initial product launch.

Action

Each document, whether a spreadsheet, document, diagram, or photograph, was secretly watermarked with a special secret code. At the same time, the main security group created an organizational unit within their main LDAP application. This was the only group that had permission to access the watermarked files. At the same time, a DLP application agent was rolled out to the computer assets within the organization. If anyone "found" a marked file and tried to do something with it, unless they were in the privileged group, access was denied *and* an alert (see Figure 67.2c) went back to the main DLP reporting server.

Result

The electronics manufacturer was able to deliver its revolutionary product to market in a secure manner and on time.

Much like the different flavors of DLP that are available (data in motion, data at rest and data in use), conditions of the severity of action that DLP applications take on the event can vary. A good place to diagnose the

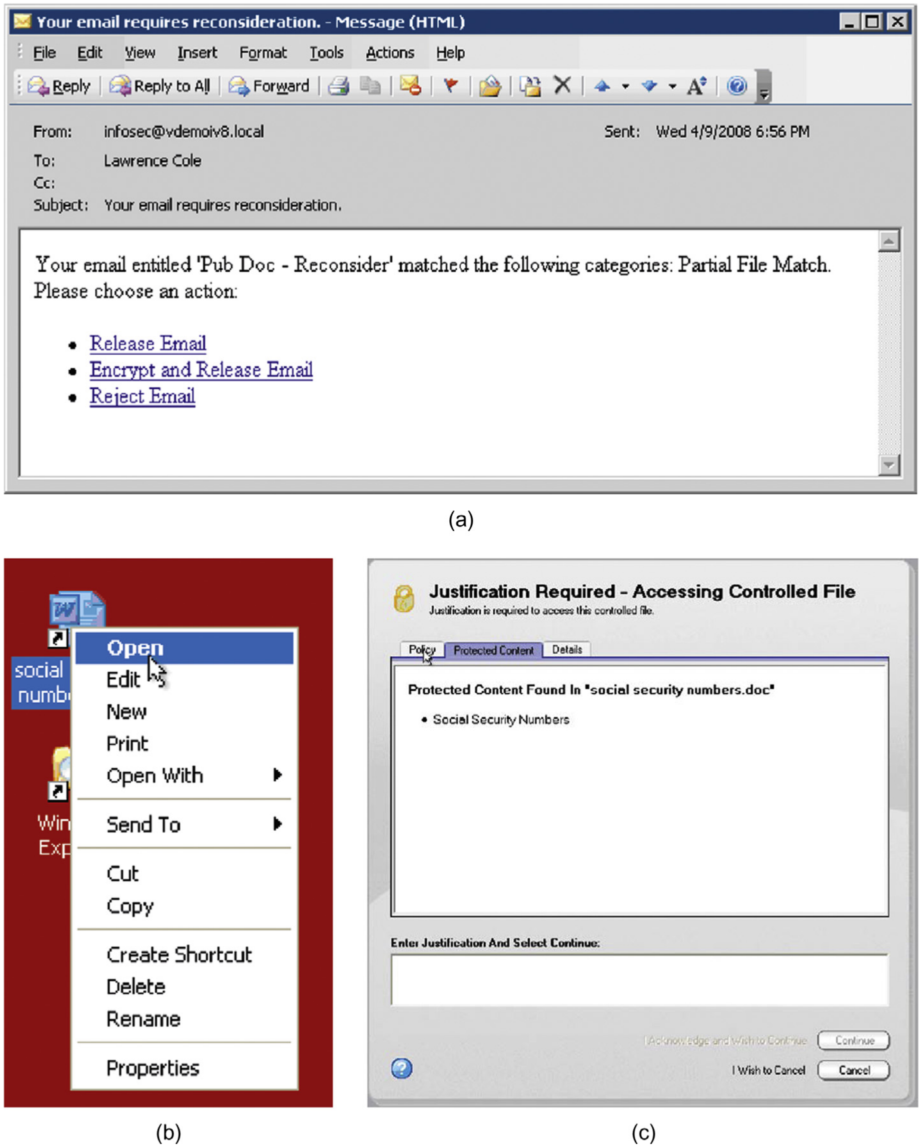

FIGURE 67.2 (a) Email with user notification on the fly; (b) PC user tries to access a protected document; and (c) policy prompts a justification alert.[5]

problems organizations are currently facing would be to start with Monitoring (see sidebar, "Case Study in Monitoring"). Monitoring is only capturing the actual event that took place to review at a later time. Most DLP applications offer real-time or near real-time monitoring of events that violated a policy. Monitoring coupled with escalation can help most organizations immediately. Escalation works well with monitoring as when an event happens, rules can be put into place on who should be notified and/or how the notification should take place. Email is the most common form of escalation.

Another action that DLP application supports is notification. Notification can temporarily interrupt that transmission of an event and could require user interaction. See Figure 67.2a for an example of the kind of "bounce" email a user could receive if she sends an email containing sensitive information. See Figure 67.2b for an example of the type of notification a user could see if he tries to open a sensitive data document. The DLP application could make the user justify why access is needed, deny access, or simply log the attempt back to the main reporting console.

Notification can enhance the current user education program in place and serve as a gentle reminder. The onus of action lies solely on the end user and does not take resources from the already thinly stretched IT organization.

The next level of severity of implementing DLP could be quarantining and then outright blocking. Quarantining events places the transmission in "stasis" for review from

Case Study in Monitoring

Background

A large data provider of financial account records dealt with millions of customer records. The customer records contained account numbers and other nonpublic, personal information (NPPI) and Social Security numbers. The data provider mandated the protection of this type of sensitive data was the top priority of the upcoming year.

Action

A DLP application was implemented. Social Security number, customer information, and NPPI categories were turned on. After one week, over 1000 data transmissions were captured over various protocols (email, FTP, and Web traffic). After investigating the results, over 800 transmissions were found to have come from a pair of servers that was set up to transmit account information to partners.

Result

By simply changing the type of transmission to a secure, encrypted format, the data was secured with no interruption of normal business processes. Monitoring was the way to go in this case and made the organization more secure and minimized the number of processes that were impacted.

a DLP administrator. The quarantine administrator can release, release with encryption, block, or send the event back to the offending user for remediation. Blocking is an action that stops the transmission in its entirety based upon the contents.

Both quarantining and blocking should be used sparingly and only after the organization feels comfortable with the policies and procedures. The first time an executive tries to send a transmission and cannot because of the action set forth in the DLP application, the IT professional can potentially lose his job.

8. IT'S A FAMILY AFFAIR, NOT JUST IT SECURITY'S PROBLEM

The IT organization does and most likely maintains the corporate email system; almost everyone across all departments within an organization uses email. The same can be said for the DLP application. Even though IT will implement and maintain the DLP application, the events will most likely come from all different types of users across the entire organization. When concerning events are captured and there will be many captured by the DLP application, most management will turn to IT to resolve the problem. The IT organization should not become the "police and judge." Each business unit should have published standards on how events should be handled and escalated.

Most DLP applications can segregate duties to allow non-IT personnel to review the disposition of the event captured. One way to address DLP would be to assign certain types of events to administrators in the appropriate department. If a racial email is captured, the most appropriate department might be a Human Resource employee. If a personal information transmission is captured, a compliance officer should be assigned. IT might be tasked if the nature of the event is hacking related.

Users can also have a level of privilege within the DLP application. Reviewers can be assigned to initial investigations of only certain types or all events. If necessary, an event can be escalated to a reviewer's superior. Users can have administrative or reports-only rights.

Each of these functions relates to the concept of workflow within the DLP application. Events need to be prioritized, escalated, reviewed, annotated, ignored and eventually closed. The workflow should be easy to use across the DLP community and reports should be easily assessable and created/tuned. See Figure 67.3a for an example of an Executive Dashboard that allows the user to quickly assess the state of risk and allows for a quick-click drill down for more granular information. Figure 67.3b is the result of a click from the Executive Dashboard to the full content capture of the event.

9. VENDORS, VENDORS EVERYWHERE! WHO DO YOU BELIEVE?

At the end of the day the DLP market and applications are maturing at an incredible pace. Vendors are releasing new features and functions almost every calendar quarter. In the past, when monitoring seem sufficient to diagnose the central issue of data security, the marketplace was demanding more control, more granularity, easier user interfaces, and more actionable reports, as well as moving the DLP application off the main network egress point and parlaying the same functionality to the desktop/laptops, servers, and their respective end points to document storage repositories and databases.

In evaluating DLP applications, it is important to focus on the type of underlying engine that analyzes the data and then work up from that base. Next rate the ease of configuring the data categories and the ability to preload certain documents and document types. Look for a mature product with plenty of industry-specific references. Company stability and financial health should also come into play. Roadmaps of future offerings can give an idea of the features and functions coming in the next release. The relationship with the vendor is an important requirement to make sure that the purchase and

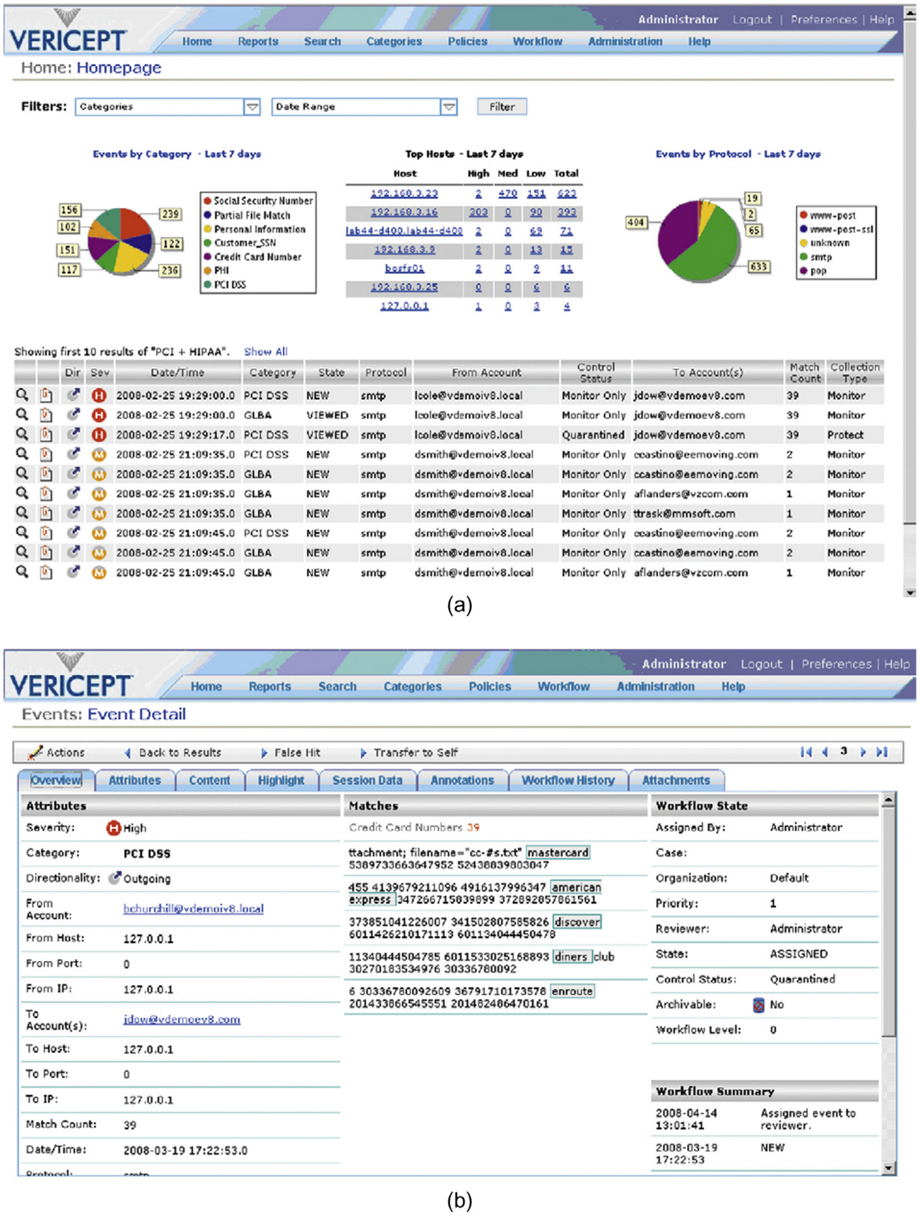

FIGURE 67.3 (a) Dashboard; (b) Email Event Overview.[5]

subsequent implementation goes smoothly. The vendor should offer training that empowers the IT organization to be somewhat self-sustaining instead of having to go back to the vendor every time a configuration needs to be implemented. The vendor should offer best practices that other customers have used to help with quick adoption of policies. This allows for an effective system that will improve and lower the overall risk profile of the organization. Analyst briefings about the DLP space can be found on the Internet for free and can provide an unbiased view from a third party of things that should be evaluated during the selection process.

10. SUMMARY

DLP is an important tool that should at least be evaluated by organizations that are looking to protect their employees, customers, and stakeholders. An effectively implemented DLP application can augment current security safeguards. A well thought out strategy for a DLP application and implementation should be designed first before a purchase. All parts of the organization are likely to be impacted by DLP, and IT should not be the only organization to evaluate and create policies. A holistic approach will help foster a successful implementation that is

supported by the DLP vendor and other departments, and ultimately the employees should improve the data risk profile of an organization. The main goal is to keep the brand name and reputation of the organization safe and to continue to operate with minimal data security interruptions. Many types of DLP approaches are available in the market today; picking the right vendor and product with the right features and functions can foster best practices, augment already implemented employee training and policies, and ultimately safeguard the most critical data assets of the organization.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The disgruntled insider, working from within an organization, is a principal source of computer crimes.
2. True or False? Even before DLP became a concept, IT organizations have not been practicing the tenets of DLP for years.
3. True or False? Data loss protection is a term that has percolated up from the alphabet soup of computer security concepts in the past few years.
4. True or False? A unreasonable place to begin talking about DLP is with the department of the organization that handles corporate policy and/or governance.
5. True or False? Employees are given data "pipes" to not do their jobs with enabling technology provided by the IT organization.

Multiple Choice

1. Embarking on a ____________ evaluation or implementation can be a straightforward exercise.
   A. Reputation
   B. Internet filters
   C. DLP
   D. Encrypted
   E. Content-control software
2. What occurs when the DLP application-monitoring or DLP application-blocking techniques wrongly classify a legitimate transmission or event as "uninteresting" and, as a result, the event must be remediated anyway?
   A. Opinity
   B. Web content filtering
   C. Scale
   D. False positive
   E. Active monitoring
3. The way that most DLP applications capture interesting events is through different kinds of:
   A. Organizations
   B. Rapleaf
   C. Analysis engines
   D. Content
   E. Security
4. There are many different forms of DLP applications, depending on the velocity and location of the:
   A. Keyword lists
   B. Denial of service attack
   C. Sensitive data
   D. Port traffic
   E. Taps
5. What is an easy place to start implementing a DLP application because most can function in "passive" mode, meaning it looks at only a copy of the actual data egressing/ingressing the network?
   A. Systems security plan
   B. TrustPlus
   C. Denying service
   D. Decision making
   E. Data in motion

EXERCISE

Problem

Data loss protection should be designed to help you improve endpoint security. With implementation, managed security services and software, you should be able to protect sensitive data that is accessed, stored and transmitted on your endpoint devices. In other words, you should be able to do what else to protect your data?

Hands-On Projects

Project

You need to prevent sensitive data loss across your network without introducing complexity to the IT environment. You should also be able to provide a comprehensive solution that helps prevent data loss through enhanced visibility and control of all network ports and internal traffic. In other words, you should be able to do what else to protect your data?

Case Projects

Problem

You need to protect business data at rest, in motion, and in use, even beyond the enterprise network-without

increasing complexity in your IT environment. You should also be able to use PGP encryption to provide a comprehensive solution that helps protect sensitive data across endpoints, removable storage media, and e-mail, against loss or unauthorized access. In other words, you should also be able to do what else to protect your data?

Optional Team Case Project

Problem

You need visibility into your information and how it is handled in order to protect sensitive data on endpoints against loss and unauthorized access. You should also be able to provide a comprehensive solution designed to automatically discover and classify sensitive data on desktops and servers, and monitor the data as it is used and exchanged. The solution helps enforce corporate security policies in realtime and reduces the risk of data loss or misuse. In other words, you should also be able to do what else to protect your data?

Chapter 68

Satellite Cyber Attack Search and Destroy

Jeffrey Bardin
Treadstone 71 LLC

In the movie *Enemy of the State*, satellites play a vital role in making the viewer believe in the ultimate power of the National Security Agency (NSA). Satellites are repurposed and moved around the sky in moments. They peer down from the heavens tracking the hero's movements, able to determine tiepin logos and license plate expiration dates. Viewers are made to believe that satellites are God-like, roving the atmosphere, seeing everything we do. The NSA does employ satellites for signals and other intelligence; however, it is the National Reconnaissance Office (NRO) that normally owns and operates U.S. spy satellites. The closest Hollywood has come to reality in spy satellites was during the movie *Patriot Games* when Harrison Ford had to look at images through a microscope trying to ascertain the identity, much less the gender of people in the photographs. Grainy images with shadows that look like other images is more in line with reality.

When thinking of satellites, thoughts often drift to Hollywood's images and the surveillance aspects of their capabilities. However, satellites play many roles in society. They provide methods for communication and remote sensing of critical infrastructures, deliver global positioning systems for navigation, keep us occupied with broadband for entertainment, and support mechanisms for videoconferencing and telemedicine. We never see them, but they are essential components in daily human activity. According to the Satellite Industry Association, nearly 37% of all operational satellites are used for business communications. Civil communications accounts for 11%, military communications for 9%, military and surveillance 9%, navigation 8%, remote sensing 9%, and meteorological 4%. The Satellite Industry Association also maintains information on world satellite industry revenue. Satellite growth increased significantly between 2005 and 2011 at an average of 11% per year in growth. The Satellite Industry Association states that satellite services continue to represent the single largest industry sector driven by satellite-TV growth at around 10% [1]. Space launch industry and satellite manufacturing revenues reflect a history of aggregate growth by yearly fluctuation, while ground equipment revenue growth reflects slight but relatively consistent year-on-year consumer and network equipment sales. It is safe to say that satellites play a prominent role in everyday life.

Very Small Aperture Terminals (VSATs) are prevalent in everyday lives. They consist of a parabolic dish and associated hardware and software. The purpose is to send and receive (uplink and downlink) signals via a satellite. They dot the landscape on homes, recreational vehicles, and boats. Human reliance on satellites is growing at an exponential rate. As with any growing commercial opportunity, security is less than the primary concern. Economics drives the opportunity.

1. HACKS, INTERFERENCE, AND JAMMING

April of 2007 started a series of issues with satellites. Tamil rebels in Sri Lanka were accused of hacking the Intelsat satellite positioned over the Indian Ocean for communicating propaganda [2]. Intelsat responded, indicating this to be a case of signal piracy (not hacking) that would not be tolerated. In a response to the Intelsat press release, the Tamil Tiger rebels indicated that they were not accessing the satellite illegally and that therefore no signal piracy had occurred. The rebels intimated a relationship with the service provider for the satellite but would provide no further explanation [3].

In 2007, the media reported that NASA satellite Landsat-7 used for ground mapping was hacked, experiencing 12 minutes of interference [4]. The same article goes on to state that in 2008, another NASA satellite, Terra AM-1 was hacked for 2 minutes in June and for 9 minutes in October. The problem with the articles and subsequent follow on by the media as well as the NASA Office of Inspector General is the depiction that the satellites were hacked. These two events were not cyber-related events but events characterized by the interference and jamming of radio signals in order to disrupt satellite send and receive transmissions. The point to be

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00068-4

made here is that this had nothing to do with cyber security but rather with traditional satellite communication protocols using radio transmissions.

Recently, there have been writings on the Internet of the potential for hacking NASA satellites to access the Curiosity land rover on Mars. Although this is pure speculation, much discussion has occurred due to the subject. The initial topic focused on the pushing of updates to change Curiosity's payload. The idea would be to intercept or to a play man-in-the-middle attack against communications between satellites and the rover. Although highly unlikely, the impact would be significant should such an activity occur. It highlights a renewed focus on satellites as objects for disruption of command, control, communications, and computers. The Jet Propulsion Laboratory (JPL) in Pasadena, California, houses the scientists, engineers, specialists, and mission control center for Curiosity. NASA missions employ a highly compartmentalized framework for computer systems tied to the mission. They are self-contained systems located in self-contained buildings running variations of operating systems or operating systems created specifically for the mission at hand, operated by personnel vetted on several levels. Once a configuration of the operating system, firmware, or other related software is proven to work per the specifications of the designers and engineers, the configuration is locked down as a module ready for execution. It is highly unlikely that a hack or intercept of the encoded transmission between JPL mission control in Pasadena and the Curiosity rover on Mars could occur. Such an unlikely occurrence would have an enormous impact on the mission. But the mission of discovering life on another planet is hardly a target for exploitation that a foreign intelligence service would undertake. It is more likely that a foreign intelligence service would target earth-born operations.

In October 2011, Creech Air Force Base was the subject of a malware attack on the Predator and Reaper drones. It was reported that a keystroke logger infected the ground control stations for drones operating in the Afghanistan theater. The malware proved to be a resilient strain that continued to reoccur after multiple system cleanings. The malware was most likely created by a foreign nation-state intent on learning as much information as possible about the United States' drone activities. What was not stated in the press is the fact that the 30th Reconnaissance Squadron of the United States Air Force operates out of Creech AFB. This is significant since this squadron operates the RQ-170 Sentinel UAV. The same UAV captured by Iran a mere two months after the keystroke logger event at Creech AFB. In what could be termed a coincidence, Iran stated that its Army's electronic warfare unity had downed an RQ-170 violating Iranian airspace by overriding the UAV's controls. An Iranian engineer later stated that Iran used GPS coordinate spoofing, fooling the UAV into thinking it was landing at an air base in Afghanistan. The Iranian engineer further claimed that it was quite easy to exploit the navigational weakness in the drone system. It is possible that signal jamming of the encrypted channels used by the military forced the UAV to revert to a communications failover process that used unencrypted methods to communicate [5]. Once the failover took place, Iranian engineers were able to manipulate the drone GPS. If the Iranian claim of control override is true, the keystroke logging event at Creech AFB takes on new meaning for cyber security surrounding ground control stations for satellite-based weapons systems. Unsubstantiated claims of Russian or Chinese intelligence services actually executing the keystroke logger and subsequently the downing of the RQ-170 become a potential premise that should be explored further. It demonstrates the need for improved cyber security measures for each component of the satellite command and control ecosystem. It also demonstrates that traditional cyber security countermeasures are not sufficient to prevent penetration or malware infection, or both. In most cases, ground control stations are air-gapped from other networks. Air gapping is a method of security control that delivers network compartmentalization, keeping all networks and devices not required to operate, manage, monitor, and/or control a sensitive system entirely separate. This is usually accompanied by stringent rules related to the use of removable media. It has been intimated that infected nonauthorized hardware was attached to the air-gapped system, providing for the infection of the target ground control stations. Malware of this type with a keystroke logger payload is used for cyber intelligence collection for later disposition and cyber countermeasures to be deployed by the initiating entity. The ability for the malware to communicate data collection efforts back to a collection hub also requires additional review since the methods of cyber security detection are often devised to keep perpetrators out, and not to prevent them from leaving as an additional level of security. It is interesting to note that a 2002 GAO report specifically warned of spoofing as a content-oriented threat for commercial satellites and the unauthorized modification or deliberate corruption of network information, services, and databases, including malicious software implanted into computer systems referencing ground control stations as a target [6]. Just under 10 years later, we have experienced exactly what the GAO warned against.

In June 2012, a group of researchers at the University of Texas at Austin used the spoofing method described by the Iranians to hack the GPS system of a drone. This demonstrates the viability of the claim and presents another issue for concern: Adversaries have the ability to

both commandeer and use the drones as flying missiles whether armed or not. The cost to spoof the drone was reported to be in the range of £700 or about $1100. This ratio of cost to the potential impact is a cornerstone of asymmetric warfare exhibited by Al-Qa'eda on 9/11. Questions over what security controls were or were not in place continue as U.S. military authorities maintain a tight lid on the exact problems and remediation methods employed since the downing of the RQ-170. Additional rumors surfaced that Iran overrode the RQ-170 self-destruct capabilities, while others have claimed no such capabilities exist on the drone.

A few years ago, a $29 program called SkyGrabber (as shown in Figure 68.1) made the news. SkyGrabber allowed interception of packet radio service from a laptop connected to a small satellite. Insurgents in Iraq (as shown in Figure 68.2) were using and training others to use the SkyGrabber software to intercept satellite and small drones communications used to scout positions of enemies prior to special forces or military activities in that particular area. Insurgents were able to intercept these communications with the $29 program largely because of lack of security over the communications between satellite and drone. This flaw was actually well known by the designers of the system. They did not apply the appropriate security controls because applying encryption to the process slowed the communications down to the point where they thought it was not effective. Regardless of their decision, insurgents intercepted this information for quite some time before being discovered. SkyGrabber uses what is called general packet radio service or GPRS. GPRS is a nonvoice service that is added to networks over 2.5- to 3-gigabit wireless communications. Consumers know this as 3 G or 4 G speeds [7]. The service uses IP transmissions to its advantage. Because Internet Protocol (IP) traffic is made of packets, the network does not need to have continuous data transmission. Each channel is divided eight timeslots, with a maximum data transmission of 13.4 kb per second. One

FIGURE 68.1 Jihadist use of SkyGrabber.

FIGURE 68.2 SkyGrabber .

of these timeslots is used for control, and normal allocation reserves two slots for voice traffic as well. Asymmetric traffic (more downloads and uploads) dictates the distribution of the remaining timeslots.

Requests are sent via the LAN connection, while responses are received from the satellite; since requests are usually small and responses are large, a narrowband connection is quite enough for requests. At the same time, responses were received at a high rate of 4 MB per second, which makes working with the Internet comfortable. If there is no encryption, it is open for interception. When the activity of the insurgents using SkyGrabber was made public, many pundits and even cyber security professionals called this interception hacking. What needs to be understood is that this was not a hack since there was in fact, nothing to hack. Without encryption, the communication mechanism is open for interception. Hacking refers to the reconfiguring or reprogramming of the system to function in ways not facilitated by the owner, administrator, or designer. The term has several related meanings in the information technology industry. A hack may refer to a clever quick fix to a computer program problem or to what may be perceived to be a clumsy solution to a problem. The terms *hack* and *hacking* are also used to refer to a modification of the programmer device to give the user access to features that were otherwise unavailable such as to do-it-yourself circuit bending [8]. It is from this usage that the term *hacking* is often incorrectly used to refer to more nefarious criminal uses such as identity theft, credit-card fraud, or other actions categorized as computer crime. Since there is a distinction between security breaking and hacking, a better term for security breaking would be *cracking* [8]. As we already know, responses are received from the satellite. However, the satellite cannot send data specifically to a particular user and so instead sends data to all dishes that receive a signal from it. Therefore, if you have the proper equipment, the signal is just waiting in the airwaves to be had.

As already surmised, it is not enough to position a small satellite dish, and that dish will also receive a signal with the same data that other satellites receive. The satellite dish may get the signal, but the question remains as to how to extract data from the intercepted signal. That is the purpose of the SkyGrabber program. The program captures what other satellite dishes download and saves the captured information to a laptop. Internet access is not required for this interception. The satellite dish needs to be rotated toward the provider, and the SkyGrabber program, with some configuration, will perform the data extraction. If the transmission is encrypted or encoded, the data extraction is prevented.

As with any information technology, information security and information assurance need to be built in from the beginning. Cyber security professionals have been stating this for years. Regardless, it seems that in the satellite industry as in many others, information security controls will not be built in until such time as a painful breach has occurred. This has been the standard mode of operation for designers, developers, and engineers for years.

Identifying Threats

In 1998 when Presidential Decision Directive 63 was originally issued, satellites were not included in the nation's critical infrastructures. This was seen as a significant oversight in the satellite industry. The General Accounting Office (GAO) report in 2002 referenced issues concerning security around satellites and covered several different areas concerning security. The GAO report covered secure data links and communication ground stations. The report also discussed issues surrounding the use of satellites that have certain security controls especially established to enhance the availability of the satellite. Since the release of that report in 2002, much has been done to bolster the security of satellites. Satellites consist of ground station tracking and control links, which are referred to as a tracking telemetry and control (TT&C) links and data links and satellites. The GAO report examined unintentional threats to commercial satellite systems and divided the threats into three different areas:

1. Ground-based threats
2. Space-based threats
3. Interference-oriented threats [6]

Examples of the ground-based threat could be naturally occurring ones such as acts of God, earthquakes, hurricanes, tornadoes, and floods. Space-based threats could be related to solar activity, different temperature variations, and different types of space debris as more countries launch satellites. Interference-oriented threats to commercial satellite systems focus more on information technology. This deals with unintentional or intentional human interference caused by terrestrial and space-based wireless systems or computer systems intended to cause harm. The interference- and content-oriented threats that are intentional threaten commercial satellite systems with malicious software, denial-of-service attacks, distributed denial-of-service attacks, service moving data interception, and potential man-in-the-middle attack methods. This includes the jamming of communications between ground stations and satellite systems. Over the years, the United States government has worked to ensure the confidentiality, integrity, and availability of satellite systems, although the focus on security is limited based on risk. The likelihood of such an attack has not been high, although attacks are increasing each year as more

attention is given to satellites. Since the attacks have not been of paramount concern, satellites related to cyber security controls have been limited in scope and function. It is probable that security controls will increase directly with the increase of threats and validated exploitation.

Communicating with Satellites

There are several methods for communicating with satellites. Many commercial satellites use baseband signals, a method that allows for only one car on the road at a time so to speak. Only one transmission either from the ground station to the satellite or from the satellite to the ground station can occur at a time. Direct broadcast satellites (DBS) is common to consumers. DBS is used by vendors such as DISH and DirecTV. DBS transmissions use various methods to secure the data transfer:

- Basic Interoperable Scrambling System, usually known as BISS, is a satellite signal scrambling system developed by the European Broadcasting Union and a consortium of hardware manufacturers. Prior to its development, "ad-hoc" or "Occasional Use" satellite news feeds were transmitted either using proprietary encryption methods (PowerVu) or without any encryption. Unencrypted satellite feeds allowed anyone with the correct equipment to view the program material.
- PowerVu is a conditional access system for digital television developed by Scientific Atlanta [1]. It is used for professional broadcasting, notably by Retevision, Bloomberg Television, Discovery Channel, AFRTS, and American Forces Network. PowerVu is also used by cable companies to prevent viewing by unauthorized viewers. PowerVu has decoders that decode signals from certain satellites for cable distribution services. These decoders can also be used just like the FTA (Free-To-Air) satellite receivers if properly configured. PowerVu is considered highly secure since it uses a complicated system to authorize each PowerVu receiver and trace its history of ownership and usage. Most PowerVu users are professional cable or satellite companies, using the service and equipment for signal redistribution, because regular users cannot afford it. On March 10, 2010, the hacker called Colibri published after previous work done in 2005 a cryptanalysis of a PowerVU system implementation. The hacker described a flawed design that can be used to gain access to the encryption keys and ultimately decrypt the transmitted content.
- DigiCipher 2, or simply DCII, is a proprietary standard format of digital signal transmission and encryption with MPEG-2 signal video compression used on many communications satellite television and audio signals. The DCII standard was originally developed in 1997 by General Instrument, which is now the Home and Network Mobility division of Motorola [9]. The original attempt for a North American digital signal encryption and compression standard was DigiCipher 1, which was used most notably in the now-defunct PrimeStar medium-power direct broadcast satellite (DBS) system during the early 1990s. The DCII standard predates wide acceptance of DVB-based digital terrestrial television compression (although not cable or satellite DVB) and therefore is incompatible with the DVB standard [9]. The primary difference between DigiCipher 2 and DVB lies in how each standard handles SI, or System Information. DigiCipher 2 also relies on the fact that its signals must be understood in terms of a virtual channel number in addition to the DCII signal's downlink frequency, whereas DVB signals have no virtual channel number [9]. Approximately 70% of newer first-generation digital cable networks in North America use the 4DTV/DigiCipher 2 format. The use of DCII is most prevalent in North American digital cable television set top boxes. DCII is also used on Motorola's 4DTV digital satellite television tuner and Shaw Direct's DBS receiver [9].

Scrambling and de-scrambling equipment for cable and satellite televisions has been the norm for over 30 years. The solutions have evolved over the years to more advanced solutions for DBS.

There are other encryption methods for DBS such as the use of smart cards allowing a single user to access television shows based on the smart card, receiver hardware, and associated software that securely and accurately identifies the users and their individual subscriptions. This is truly commonplace in the commercial market. Advances have been made to incorporate the Advanced Encryption Standard (AES) in satellite transport networks, providing much greater security using encryption keys. Regardless of the security solution in use, the intent is to protect pay-TV signals enforcing subscription-based access to available programs.

Improving Cyber Security

According to a 2009 report from IGI Global as written by Marlyn Kemper Littman titled "Satellite Network Security," satellite transmissions are subject to lengthy delays, low bandwidth, and high bit-error rates that adversely affect real-time, interactive applications such as videoconferences and lead to data corruption, performance degradation, and cyber incursions [10]. Littman goes on to say that multiple layers of security covering all aspects of the satellite's ecosystem is needed to adequately protect satellite networks. This includes policies

and legislation requiring minimum necessary security protocols and standards. The Defense Information Systems Network (DISN) Satellite Transmission Services Global (DSTS-G) Performance Work Statement states that:

DODD 8581.1E requires that commercial satellites used by the Department of Defense employ NSA-approved cryptography to encrypt and authenticate commands to the satellite if supporting Mission Assurance Category (MAC) I or II missions as defined in DoD Directive 8500.1. While NSA approved cryptography is preferred for satellites supporting MAC III missions, cryptography commensurate with commercial best practices is acceptable for encrypting and authenticating commands to satellites that only support MAC III missions.

The change in cryptography requirements is for commercial interoperability with DOD satellite systems. These changes went into effect in 2005 and represent a shift to encrypt using the latest technologies transmitted over higher bandwidth, using mission-specific data networks. The change also calls for continued modifications to the security environment as new threats appear and new solutions are available. The cryptography requirements directly align to the Satellite Internet Protocol Security or SatIPSec initiative from 2004. This protocol provides for encrypted transmissions using a standard symmetric method that clearly identifies the sender and receiver. SatIPSec used in conjunction with the Satellite-Reliable Multicast Transport Protocol (SAT-RMTP), which provides secure transmission methods for audio and video files, enhances the satellite ecosystem security posture.

There are several areas for improvement in satellite cyber security. As with many commercial ventures, the sharing of information is limited due to the potential for leaking intellectual property or proprietary processes, procedures, and methods. The information and cyber security industry is rife with examples of limited information sharing. Most companies are remiss to share information on breaches due to the potential embarrassment public awareness could bring. What is missed is the opportunity to share remediation strategies and information on the attacker. This actionable intelligence could prevent other organizations from suffering the same fate. Methods of remediation that are successful should be shared across the satellite industry and within federal and state governments. The opportunity to share effective security practices could vastly improve satellite cyber defenses. Information sharing coupled with the appropriate education and awareness-raising efforts for the satellite industry is an effective method of propagating actionable intelligence.

Until recently, organizations did not agree on what represented an attack. The underlying issue is the use of a common taxonomy relative to satellite security. Incorporating already defined words, phrases, and concepts from the information security community can and will speed up the adoption of and integration of a common book of knowledge (CBK) surrounding satellite cyber security. Just as Web sites and applications on the Internet are subject to continuous probes, scans, denial of service, and distributed denial-of-service activity, the satellite industry faces continuous intentional interference and jamming. The satellite industry could learn how to adopt methods of interference and jamming prevention by incorporating proven principles and methods achieved over years of parallel activity on the Internet. Additionally, organizations managing satellites need to distinguish between advertent and inadvertent events and events that are intentional and unintentional. The data points gathered by the scores of government and commercial satellite organizations worldwide could be organized into information that is analyzed for links, tendencies, and trends to help devices' ever-changing defenses to transmission penetration and jamming. The underlying premise is information sharing for the benefit of nonhostile entities to improve their defensive, preventive, and even predictive countermeasures through intelligence analysis of satellite-specific data points using proven methods in cyber security. An organization such as the National Council of Information Sharing and Analysis Centers (ISAC) could sponsor or propose an ISAC specific to the satellite industry adopting proven methods across the member ISACs to assist in information-sharing activities. The Communications ISAC could further expand into the satellite industry with very specific goals, emphasizing sharing information used to mitigate and prevent typical satellite-related impacts to confidentiality, integrity, and availability.

Many members of the cyber security industry may overlook the physical security aspects of satellite security. Like any centralized management function, satellite monitoring and maintenance is performed from a ground location. Data centers require hardened perimeters and multiple layers of redundancy. Satellite ground controls stations require the same level of attention to security detail. These facilities should have standardized CCTV and access control methods. Security guards performing 24×7 monitoring and response and employee training and awareness programs must be in place. Many ground control stations are not equipped to withstand electromagnetic plus radiological fallout, or instances of force majeure. They lack what many in the information technology industry would term standard requirements for availability. Furthermore, many ground control stations are within proximity of public areas, providing potentially easy access for those with malicious intent. Standards for the continuity of operations for ground control stations should include conditioned and generated power, as well as backup locations in varied geographic locations with

an inventory of equipment available in case of an incident.Ground control centers should also practice disaster recovery and business continuity through regularly scheduled exercises. The points mentioned herein are standard functions of an information technology data center that can and should be applied to the satellite industry. All ground control stations should have centralized and backup network operations, security operations, and satellite operations centers integrated into a cohesive monitoring and data-sharing environment.

Several “anti” solutions should be tested and embedded in each satellite’s ecosystem based on risk. Sensitive or military satellites should be required to consistently and continually provide antijamming, antispoofing and antitampering capabilities that can be monitored by the ground control station. Ground control stations need to be outfitted with prevention-based cyber security solutions that either prevent or detect penetrations, prevent malware and data exfiltration, and monitor, record, and analyze malware characteristics.

Another concept for all U.S.-based satellites is the use of all appropriate satellites to act as a sensor while in orbit. The idea is for each satellite to share information on surveilled targets after agreeing to install a government payload or sensor that provides a space-based surveillance and warning network. This concept borrows from cyber security technologies using sensors to monitor network activity across government or commercial entities. The government could offer some type of concession or support to the commercial organization in exchange for carrying the nonintrusive payload.

Although many of the recommendations are already a regular occurrence in military satellite systems, commercial systems do not necessarily require the same level of security or scrutiny. Regardless, recent interference and jamming of satellite-controlled device under the military’s purview and the penetration of malware of ground control stations indicate a need for increased attention to security whether it is cyber or of a more traditional need. A call for all satellite ecosystems to undergo assessment and authorization procedures as defined in the Federal Information Security Management Act (FISMA) and as detailed on the DoD Information Assurance Certification and Accreditation Process (DIACAP) may be warranted based on the role satellites play in critical infrastructures. The use of DIACAP and DSTS-G can help drive cyber security framework standardization for satellites (see checklist: An Agenda for Action for Implementing Cyber Security Framework Standardization Methods for Satellites). They can help drive mitigation measures using onboard satellite radio frequency encryption systems.

When it comes to ground-based network operations centers (NOC) and security operations centers (SOC), traditional cyber security standards and controls apply for both physical and virtual measures. Much the same applies to interference. Interference in the satellite ecosystem comes from several sources such as human error, other satellite interference, terrestrial interference, equipment failure, and intentional interference and jamming [11].

The satellite industry continues to take steps to mitigate and deliver countermeasures to the various types of interference. Use of various types of shielding, filters, and regular training and awareness can help reducemost types of interference. Intentional or purposeful interference (PI) is not remediated through these measures. The satellite industry has created an information technology mirror process and procedure called the Purposeful Interference Response Team or PIRT. Many of the same methods, processes, and procedures used in a computer emergency response team (CERT) program have been adopted for use in the PIRT.Root cause analysis of PIRT incidents is shared back into the process and out to satellite owners to ensure effective security practices and countermeasures are shared across the industry. Communications and transmission security measures are employed using standards such as those defined by the National Institutes of Standards and Technology (NIST) and its Federal Information Process Standard (FIPS) 140−2.

An Agenda for Action for Implementing Cyber Security Framework Standardization Methods for Satellites

Standardization can introduce methods such as carrier lockup, uniqueness, autonomy, diversity, and out-of-band commanding (check all tasks completed):

_____**1.** Carrier lockup is a method used to maintain steady and continuous communication between satellite and the ground control stations ensuring no other transmissions can be inserted from unauthorized ground control stations [11].

_____**2.** Uniqueness provides each satellite with a unique address much like a personal computer’s media access control (MAC) address [11].

_____**3.** Autonomy is a predefined protocol of self-operation, giving the satellite the capability to operate autonomously for certain periods should there be some type of interference or jamming [11].

_____**4.** Diversity provides diverse and redundant routes for transmitting data much like the use of multiple Internet connections from different providers in a data center [11].

_____**5.** Out-of-band commanding provides unique frequencies not shared by any other traffic or ground control stations [11].

As the satellite industry continues its move toward traditional information technology-type hybrid networks, satellites will be subjected to the same types of IT vulnerabilities that ground-based systems suffer today. The issues associated with this migration are apparent, but so too are the solutions. Cyber security standards, processes, procedures, and methods are available without the need for creating them anew. Regardless, their application is required in the design phase of the satellite ecosystem in order to be fully effective. Onboard IT systems provide greater features and real-time modifications, but they also introduce traditional IT vulnerabilities and exploits if not managed properly.

2. SUMMARY

Contrary to what is portrayed in Hollywood, satellites cannot be immediately retasked, nor can they see and hear everything humans do. Satellites have progressed substantially over the years, providing society with cell phone services, pay-TV solutions, hand-held global position systems, GPS for automobiles, motorcycles, and boats, telemedicine, and law enforcement. Satellites play roles in society that are now commonplace. The ubiquitous nature of satellites combined with advances in computing power and capabilities is a double-edged sword for satellite ecosystems. The last several years have seen a parallel increase in satellite deployments and efforts to purposefully interfere with satellites, jam satellite transmissions, and penetrate components of the satellite ecosystem with malicious code. In many cases, radio frequency interference and jamming has been confused as hacking. This may change in time as satellites increase the use of onboard computer capabilities with remote updating needs and patching requirements, much like land-based information technology systems. Foreign intelligence services continue to target U.S. satellite ecosystems in particular, with ground control stations as the least path of resistance method of penetration for traditional computer hacking and malware distribution. Once penetrated, the malware can perform various tasks based on its payload. To date, the payload has been intelligence gathering. Future penetrations could result in cyber sabotage or terrorist activities, resulting in the loss of life and disruptions to critical infrastructures.

The need to build cyber security into satellite ecosystems can remediate risk at inception. The risk-based approach, heavily reported to be the best method of cyber security posture management, could in fact be nothing more than a step in developing a cyber security life cycle—a life cycle that could mature appreciably by transparently embedding cyber security into every facet of every process, procedure, method, and component of the satellite ecosystem.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Very Small Aperture Terminals (VSATs) are prevalent in everyday lives.
2. True or False? Recently, there have been writings on the Internet of the potential for hacking NASA satellites to access the Curiosity land rover on Venus.
3. True or False? In October of 2011, Wright Patterson Air Force Base was the subject of a malware attack on the Predator and Reaper drones.
4. True or False? In June of 2012, a group of researchers at the University of Texas at Austin used the spoofing method described by the Iranians to hack the stealth system of a drone.
5. True or False? A few years ago, a $29 program called SkyGrabber made the news. The program allowed interception of packet radio service from a laptop connected to a large satellite.

Multiple Choice

1. Examples of the ________________ could be those that are naturally occurring such as acts of God, earthquakes, hurricanes, tornadoes, and floods.
   - **A.** reputation
   - **B.** Internet filters
   - **C.** ground-based threat
   - **D.** encrypted
   - **E.** content-control software
2. There are several methods for communicating with satellites. Many commercial satellites use __________, a method that allows for only one car on the road at a time so to speak?
   - **A.** opinity
   - **B.** Web content filtering
   - **C.** scale
   - **D.** baseband signals
   - **E.** active monitoring
3. What is a satellite signal scrambling system developed by the European Broadcasting Union and a consortium of hardware manufacturers?
   - **A.** Basic Interoperable Scrambling System (BISS)
   - **B.** Rapleaf
   - **C.** Worms
   - **D.** Content
   - **E.** Security

4. What is a conditional access system for digital television developed by Scientific Atlanta?
   A. PowerVu
   B. Denial-of-service attack
   C. Venyo
   D. Port traffic
   E. Taps

5. What is a proprietary standard format of digital signal transmission and encryption with MPEG-2 signal video compression used on many communications satellite television and audio signals?
   A. Systems security plan
   B. DigiCipher 2 (DCII)
   C. Denying service
   D. Decision making
   E. URL lists

EXERCISE

Problem

A GAO report examined unintentional threats to commercial satellite systems. The report broke the threats into three different areas. What were those areas?

Hands-On Projects

Project

Please explain in explicit detail the Basic Interoperable Scrambling System.

Case Projects

Problem

Please explain PowerVu in explicit detail.

Optional Team Case Project

Problem

Please explain DigiCipher 2 in explicit detail.

Chapter 69

Verifiable Voting Systems

1. INTRODUCTION

Many general challenges involved in running a voting system securely are common to any complex secure system, and any implementation will need to take account of these. Over and above these challenges, we introduce a particular approach to addressing the challenge of demonstrating trustworthiness, around the key idea of end-to-end verifiability. This means that every step of the processing of the votes, from vote casting through vote tallying, can be independently verified by some agent independent of the voting system itself. In particular, the output of the system can be checked, and so the integrity of the election does not need to rely on the trustworthiness or competence of the system and its programmers, but can be demonstrated independently. *Individual verification* of a step occurs when an individual voter is able to perform some check that his vote was handled correctly. *Universal verifiability* of a step is when any external party is able to check that the step has been carried out correctly. Typically, end-to-end verifiability of a system will include both of these kinds of verifiability. Verifiability provides an assurance that the result of the election is accurate.

This chapter shows how verifiability can be provided within a voting system by introducing several verifiable voting schemes that have been proposed. Section 2 first discusses the many security requirements of voting systems and the relationships between them. As well as verifiability, requirements include ballot secrecy, integrity, coercion-resistance, and usability among others. These requirements are often in tension, and part of the challenge of designing an e-voting system is to find ways of reconciling them. Section 3 then introduces the different kinds of verifiable voting schemes. Cryptographic mechanisms are used by many schemes in order to achieve particular goals, and this is the topic of Section 4. A simple example would be to provide the voter with a receipt of how they voted in order to allow individual verifiability. In order to maintain the secrecy of the ballot (even if the voter wants to prove how she voted, for example, to sell the vote), the receipt could be encrypted to mask the information. The section introduces more sophisticated cryptographic mechanisms that are used, including secret sharing to distribute trust (no individual party has total access to a critical secret such as the election secret key); zero-knowledge proofs for verification (allowing a check that an operation on a secret has been done correctly without giving away secret information); and mixnets, to shuffle and decrypt a set of votes so that no decrypted vote can be linked to its original encryption. An overview of several noteworthy schemes are then introduced in Section 5, and the development of a particular scheme, Prêt à Voter, is introduced in Section 6 to illustrate in more detail the considerations that go into the design of a verifiable e-voting scheme. We consider threats to such schemes in Section 7 before concluding in Section 8.

2. SECURITY REQUIREMENTS

While e-voting systems often vary widely in design and operation, they generally converge on a standard set of security requirements. These requirements are difficult to capture, and there is no consensus as yet on precise definitions (see checklist: Security Requirements on Electronic Voting Systems).

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00069-6

Security Requirements on Electronic Voting Systems

Intuitive definitions of some important security properties are as follows[1] (check all tasks completed).

_____**1.** Ballot secrecy: Only the voter should know how she voted.

_____**2.** Legitimacy: Only registered voters may vote.

_____**3.** Eligibility: A voter may vote at most once and all votes cast are genuine.

_____**4.** Individual verifiability: The voter should be able to check that her vote is accurately recorded for tabulation.

_____**5.** Universal verifiability: The final tally should be verifiable by any third party.

_____**6.** Accuracy (Integrity): The announced tally should reflect the true count of all legitimate, cast votes.

_____**7.** Receipt-freeness: A voter should not be able to prove her vote.

_____**8.** Coercion resistance: A voting system is coercion resistant if the voter can vote the way she wishes to, even while appearing to cooperate with the coercer.

_____**9.** Robustness: The system should be able to deliver the correct result even in the event of certain, suitably defined, levels of failure of corruption.

_____**10.** Availability: Users should be able to access all features of a fully-functioning system during the election.

Interrelationships and Conflicts

These properties are not wholly independent. For example, ballot secrecy and anonymity can be regarded as special cases of confidentiality or privacy; individual and universal verifiability together imply integrity.

Coercion-resistance is a stronger form of receipt-freeness, which can be described as the inability of a voter to prove how she voted. For coercion-resistance to hold, the voter must be able to vote for her chosen candidates even if she appears to cooperate with the adversary during the whole voting process, from the time before the vote is cast until the final result is published.

Observe also that tension exists between certain properties, most markedly ballot secrecy and individual verifiability. While the requirement exists for ballot secrecy, it should also be possible to publicly verify the accuracy of both vote recording and tallying. It is a challenge to reconcile these two requirements.

Achieving System Security

At a high level, any verifiable supervised scheme can be divided into two parts. At the *front-end*, voters interact with the voting client to generate their encrypted votes and then submit their votes to the voting system. At the *back-end*, the received votes are tallied, and the election result is announced. Note that voters only need to be involved in the front-end, while they need not be concerned with the back-end.

Challenges

The privacy, receipt-freeness, and integrity properties need to be considered in both the front-end and the back-end. In the front-end, the voter's intent should not be leaked, even if the voter wants to prove it to others. This requires the encrypted vote to be generated at some supervised and controlled environment, such as a voting booth. Otherwise, adversaries who see how the encrypted vote is generated will learn the voter's intent. Moreover, the receipt should only contain the encrypted vote, but not the plaintext intent.[2] In the back-end, if each vote is decrypted individually at the end of the tally, the relationships between the received encrypted votes and the decrypted votes have to be kept private using mixnets. Alternatively the homomorphic property can be used to combine received encrypted votes so that no individual vote will be decrypted at the end of the tally.

In the majority of verifiable schemes, the encrypted votes are encoded using encryption algorithms. Although different key lengths can be carefully selected based on different security requirements, this only provides computational privacy. If adversaries have unlimited computational resources, they are able to decrypt the encrypted votes on the Web bulletin board (WBB) directly. Therefore, as the computational power increases and better breaking algorithms are introduced, today's encrypted votes might be decrypted some time later without using the secret key. For this reason, some researchers advocate the *everlasting privacy* property that ensures unconditional privacy that does not depend on the strength of encryption. To achieve this property, the encrypted vote could be encoded using unconditionally hiding bit commitments instead of encryption.

1. Further explanation and discussion of these properties can be found in [1].

2. Note that the Farnel scheme [2] has introduced another interesting design philosophy for the receipt. Instead of each voter being provided with a receipt that contains her own encrypted vote, the voter will be given a random receipt that contains another voter's vote. Hence the receipt can contain the plaintext intent. However, because some receipts may not be given to any of the voters and they can be removed without being detected, Farnel is not fully verifiable, and we do not discuss it further in this chapter.

Compromises

An e-voting system may only satisfy a subset of the desirable security properties. Similarly, a system may only partially satisfy a certain property, or it may satisfy a weaker form of the property.

For example, a system may be receipt-free but not coercion-resistant: A coercer may be able to obtain a voter's credentials and vote in her place. Therefore, even if the scheme is receipt-free, it is not coercion-resistant. Coercion-resistance is also difficult to achieve in remote e-voting schemes if the entire voting process is unsupervised, as there is no sure way to exclude outside influence during voting. A few solutions to the problem have been devised and are discussed later in the chapter. However, their implementation is not straightforward, and in some cases such as for complex voting methods such as Single Transferrable Vote (STV), they may be computationally infeasible in practice.

If Internet voting is required, the voting administrators may have to accept the possibility of coercion. However, coercion may not be considered a serious threat in the particular voting community. It is a case of balancing system requirements against the achievable level of security, recognizing and accepting the possible threats.

Absolute ballot secrecy is another strong requirement that is not always possible to achieve, for example, when the outcome of voting is unanimous. Likewise, a compromise may need to be reached between ballot secrecy and, for example, introducing human assistance and/or audio/visual aids for disabled voters. The threat then arises of an official and/or device "learning" a vote. If legislation demands increased accessibility, then there is no choice but to implement the (typically) strong safeguards on equipment that becomes necessary.

3. VERIFIABLE VOTING SCHEMES

In the literature, although a large number of verifiable voting schemes have been introduced and various techniques have been used in these schemes, many of them share similar design philosophies. In this section, we review some of the design philosophies for these verifiable voting schemes. Our focus is verifiable supervised schemes, but we will also briefly explain verifiable remote voting and its limitations.

Verifiable Supervised Schemes

The verifiability property consists of three components: cast-as-intended, recorded-as-cast, and counted-as-recorded. The first two components are related to the front-end, ensuring that the voter's encrypted vote is not only correctly generated but also properly recorded by the election system. The last component is related to the back-end to ensure that all received encrypted votes are correctly tallied. We now explain how these three components can be designed in verifiable supervised schemes.

To achieve the cast-as-intended property, the individual voter needs to verify that the encrypted vote contains her intended vote. One typical strategy is to use the cut-and-choose method. For example, after an encrypted vote is generated by the voting client, the voter randomly decides whether to audit it or cast it. Note that if the encrypted vote is audited, the voter should not be allowed to cast it as her vote. The voter can repeat the audit process as many times as she likes, each time using an independently generated encrypted vote. After she is satisfied, she requests another encrypted vote and submits it without auditing. The cut-and-choose method provides probabilistic assurance that the encrypted vote is correctly generated without cheating on the part of the system. Another typical strategy requires the voting client to generate a cryptographic proof that the encryption is correctly performed, and an honest voter will accept the proof if the encrypted vote is indeed properly generated.[3] This is the approach taken by MarkPledge discussed later in this section. Different from the cut-and-choose method, this direct audit gives a much higher assurance that the voting client is honest, and the voter can cast the vote that has been audited. Auditing is, however, normally more complex than the cut-and-choose method.

The two auditing methods can be illustrated using a simple analogy: Consider the problem of ensuring that an intact fortune cookie contains a fortune. Using cut-and-choose, when given a fortune cookie you can either break it open (but then it cannot be used later as a fortune cookie) and check that it contains a fortune, or you can decide to accept it. If you choose to break open several and confirm that they all contain a fortune, then you can be confident when you decide to accept one that this one will also contain a fortune. Alternatively, to cut-and-choose, you may use high-tech X-ray equipment to scan a cookie. If the result confirms the presence of a fortune, you will have very high assurance that there is a fortune in the cookie. In this way, no cookie needs to be opened, but it needs more advanced technology than the previous method.

To achieve the recorded-as-cast property, two requirements are necessary. First, there needs to be an append-only WBB that can be read by the public but can only be appended by authorized parties. Once some information is written to it, it cannot be altered or removed. In verifiable schemes, after voters submit their encrypted votes to the election system, all these votes will be published on the WBB. Second, each voter will be provided with a

3. Note that the voter should not be able to transfer this proof to others. Otherwise, this proof also proves how this voter has voted.

receipt that contains her encrypted vote. To verify that her vote has been recorded by the election system, the voter can later check her receipt against the WBB to verify that her vote has been correctly recorded by the election system. If not, she can use the receipt to support a complaint to the authorities. Note that this check is optional. But since the attackers do not know which votes will be checked, if they remove a few votes before they reach the WBB, this cheating behavior will be caught with high probability.

The counted-as-recorded property is achieved by designing the tally phase so that its entire process is publicly verifiable. In other words, no vote can be added, altered, or removed without being detected. For example, if some invalid votes need to be removed from the tally, it can be verified by the public that all invalid votes have been removed and no valid vote has been removed. Moreover, the election result is calculated using the remaining votes in a publicly verifiable way. Mixnets and homomorphic encryption are two typical techniques used in the tally phase. They not only ensure the counted-as-recorded property, but also protect ballot secrecy.

A similar notion to verifiability is *software independence*[3]: A voting system is software independent when the result it reports does not depend at all on the correctness of its software. In other words, an undetected error or deliberate change in the software cannot cause an undetected error or change to the election result. Hence the software does not need to be trusted in order to have confidence in the election result because its output can be verified for correctness. Since the software is generally the most complex and intricate element of an e-voting system, obtaining software-independence is an important counterbalance to overreliance on the correctness of the software.

Verifiable Remote Schemes

The design philosophy for verifiability is similar in both verifiable supervised and remote voting schemes. However, because voters will cast their votes in an uncontrolled environment (via Internet or post), the receipt-freeness property becomes trickier to achieve. This is because adversaries may observe the voter when she is casting her vote and find out how she has voted.

In a low-coercion environment, (coercion and vote buying are not serious concerns), the verifiable remote scheme can be directly designed based on a verifiable supervised scheme, just ignoring the receipt-freeness property. For example, the voter generates her encrypted vote and then submits it to the election system through a remote channel. She can still check that her vote is correctly generated, but without the receipt-freeness protection, she might be coerced to vote the candidate favored by adversaries. The Helios system [4] is an example of a verifiable remote scheme designed for a low-coercion environment.

The receipt-freeness property can be achieved in verifiable remote schemes, but there needs to be an untappable channel between the voter and the election system, and information transmitted through this channel is kept private from others. A popular design principle is to add a registration phase before the election day. This phase is carried out within some controlled environment, but the voter can participate in it at any convenient time. Here we briefly explain the design philosophy of the JCJ/Civitas scheme [5,6]; its technical details will be further explained later in this chapter. Each voter will register a credential in the registration phase. In the voting phase, the voter should first encrypt her credential and her preferred candidate (as well as some zero-knowledge proofs), and then submit them to the election system. Because adversaries cannot distinguish a fake credential from a real one, when the voter is being coerced, she can use a fake credential to cast a vote. Note that all votes with fake credentials will be removed from the tally in a publicly verifiable way after mixing. Later, she can cast her vote again using her real credential when she is not being coerced. However, this type of scheme also has some limitations. First, voters need to perform complicated cryptographic calculations both in the registration phase and in the voting phase. Either voters need to use some trusted device, or they need to possess special knowledge to perform these tasks. Second, if the credential is learned by any other party (by the voting client or by adversaries using social engineering), this party can cast another vote at a later time to overwrite the voter's vote.

4. BUILDING BLOCKS

In this section, we briefly describe some building blocks that are commonly used to build verifiable voting schemes. These include encryption schemes, secret sharing and threshold techniques, zero knowledge proofs, mixnets, and some other useful techniques, such as blind signature, designated verifier proof, plaintext equivalent test, and proxy re-encryption.

Encryption Schemes

In public key encryption, anyone can encrypt a message using the public key, and the encrypted message can only be decrypted by the party who possesses the corresponding secret key. Moreover, some schemes also enjoy the additive homomorphic property, which is a very handy feature in verifiable voting schemes. It allows the received encrypted votes to be aggregated into a single ciphertext. To tally the election result, only this single ciphertext is decrypted, so that no individual vote will be revealed.

RSA Cipher

The RSA cipher [7] works as follows: let p and q be two large primes, where $n = pq$ and $\phi = (p-1)(q-1)$. We first select a random value e, such that $1 < e < \phi$ and $gcd(e, \phi) = 1$. Then by applying the extended Euclidean algorithm, we can compute a value d such that $1 < d < \phi$ and $ed \equiv 1 \pmod{\phi}$. Now, the RSA public key is (n, e) and the corresponding secret key is d. To encrypt a plaintext $m \in Z_n$, we can compute the ciphertext as $c = m^e \pmod{n}$. To decrypt c, the party who knows the secret key d can compute $c^d = m^{ed} = m^{k\phi+1} = m \pmod{n}$. RSA enjoys the multiplicative homomorphic property. For example, if $E(m_1)$ and $E(m_2)$ are two RSA ciphertexts with plaintexts m_1 and m_2, then we have $E(m_1) \cdot E(m_2) = E(m_1 \cdot m_2)$. RSA is a deterministic public-key encryption scheme,[4] and its security is based on the factoring problem.

ElGamal Cipher

The ElGamal cipher [8] works as follows: Let p, q be two large primes such that $q|p-1$. We denote G_q as the subgroup of Z_p^* with order q. Let g be a generator of G_q. The secret key is an element $x \in Z_q$ and the corresponding public key is $y = g^x \pmod{p}$. In this chapter, if we apply the ElGamal parameters, we assume all arithmetic to be modulo p where applicable, unless otherwise stated. To encrypt a plaintext $m \in G_q$, we choose a random blinding factor $r \in Z_q$ and compute the ciphertext $E(m, r) = (G, M) = (my^r, g^r)$. Note that an ElGamal ciphertext is a pair of values of G_q. To decrypt the ElGamal ciphertext (G, M), we compute $m = G/M^x$. ElGamal enjoys the multiplicative homomorphic property, and it is a probabilistic public-key encryption scheme, which is semantically secure if the decision Diffie-Hellman assumption holds in the group G_q.

ElGamal re-encryption: Given an ElGamal ciphertext $(G, M) = (my^r, g^r)$, a party can efficiently compute a new ciphertext (G', M') that decrypts to the same plaintext as (G, M). We denote that the ciphertext (G', M') is a re-encryption of (G, M). To re-encrypt a ciphertext, the party chooses a value $s \in Z_q$ uniformly at random and computes $(G', M') = (G \cdot y^s, M \cdot g^s)$. We note that this does not require the knowledge of the secret key x, only the public parameters y and g are needed.

Exponential ElGamal cipher: This is a variant of the ElGamal cipher with an additional parameter h, which is also a generator of the group G_q. To encrypt a plaintext $m \in Z_q$, we randomly choose a blinding factor $r \in Z_q$ and calculate the ciphertext as $E(m, r) = (G, M) = (h^m y^r, g^r)$. The decryption process is the same as in the ElGamal cipher, but there is no efficient algorithm to retrieve the plaintext m from h^m. Instead, if m is known to be restricted within some field, we can search the field or use precomputed lookup tables to retrieve m.

The exponential ElGamal cipher can be re-encrypted in the same way. But unlike the ElGamal cipher, it enjoys the additive homomorphic property. For example, if $E(m_1)$ and $E(m_2)$ are two exponential ElGamal ciphertexts with plaintexts m_1 and m_2, then we have $E(m_1) \cdot E(m_2) = E(m_1 + m_2)$ and $E(m_1)^k = E(k \cdot m_1)$.

Paillier Cipher

The Paillier cipher [9] works as follows: Let n be an RSA modulus $n = pq$, where p, q are large primes. Let g be an integer of order a multiple of n modulo n^2. The public key is (g, n), and the secret key is $\lambda = lcm((p-1), (q-1))$. To encrypt a message $m \in Z_n$, we randomly choose $x \in Z_n^*$ and compute the ciphertext $c = g^m x^n \pmod{n^2}$. To decrypt c, we compute $m = L(c^\lambda \bmod n^2)/L(g^\lambda \bmod n^2) \pmod{n}$, where the L-function takes input values from the set $S_n = \{u < n^2 | u = 1 \pmod{n}\}$ and computes $L(u) = (u-1)/n$. Clearly, the Paillier cipher also enjoys the additive homomorphic property, but it is superior to the exponential ElGamal cipher in that it is able to retrieve the plaintext directly after the decryption.

Paillier re-encryption: Given a Paillier ciphertext $c = g^m x^n \pmod{n^2}$, we can re-encrypt it without knowledge of the secret key λ. First, we randomly select a value $t \in Z_n^*$, and then we calculate $c' = c \times t^n = g^m \{tx\}^n \pmod{n^2}$. Now, c' is an re-encryption of c.

Secret Sharing and Threshold Techniques

In secret sharing and threshold techniques, the secret information (the secret key) is shared among several parties, and a quorum of these parties can work together to recover the information. Their difference is that in secret sharing, there needs to be a trusted authority to distribute the secret information among all the parties. But in threshold techniques, no trusted authority is needed, and all parties can work together to generate the secret information and distribute it among themselves. Here, we review some basic secret sharing techniques and the threshold ElGamal. Note that the threshold RSA and threshold Paillier are also feasible, but they are more complex. Refer to [10–13] for their technical details.

Shamir's Secret Sharing

Shamir's secret sharing scheme [14] is the fundamental building block for many other secret sharing and threshold techniques. It works as follows: If we want to find out the solution of polynomial $f(z) = f_0 + f_1 z + \cdots + f_{k-1} z^{k-1}$

4. In deterministic encryption, the same plaintext will always be encrypted to the same ciphertext. In contrast, the same plaintext can be encrypted to different ciphertexts using probabilistic encryption.

of degree $k-1$, we need to find out every value of $(f_0, f_1, \ldots, f_{k-1})$. Therefore, we need to find out at least k pairs of (z_i, m_i) values such that for each pair, we have $f(z_i) = m_i$. Therefore, if we set f_0 as the secret m, we can generate any number of m_i, such that $m_1 = f(1)$, $m_2 = f(2), \ldots, m_n = f(n)$. Given any subset of k of these m_i values, we can find out all the coefficients of $f(z)$ by interpolation. But on the other hand, knowledge of at most $k-1$ of these values will not enable the calculation of f_0.

By using the Lagrange interpolation, the polynomial can be written as:

$$f(z) = \sum_{i=1}^{k}\left(m_i \prod_{j=1,\, j\neq i}^{k} \frac{z - z_j}{z_i - z_j}\right)$$

Therefore

$$m = \sum_{i=1}^{k} m_i L_i$$

where

$$L_i = \prod_{j=1,\, j\neq i}^{k} \frac{j}{j-i}$$

Verifiable Secret Sharing

Verifiable secret sharing [15] is based on Shamir's secret sharing, but it enjoys an additional advantage: All parties can verify that the secret has been properly distributed. The authority first generates the ElGamal secret key $x \in Z_q$, where $y = g^x$ and then distributes x among a number of parties using the Shamir's secret sharing. Let

$$f(z) = f_0 + f_1 z + \cdots + f_{k-1} z^{k-1}$$

where $f_0 = x$. For $i = 0, 1, \ldots, k-1$, the authority also computes each $F_i = g^{f_i}$ and makes these values public. Then the authority can destroy the secret information x. At this moment, any party can check whether her given secret share is correctly constructed. Suppose the j-th party has been assigned the share x_j. She verifies that

$$g^{x_j} = \prod_{l=0}^{k-1} F_j^{j^l}$$

If the share is properly constructed, the above equation will always hold because

$$g^{x_j} = g^{f_0 + f_1 \cdot j + \cdots + f_{k-1} \cdot j^{k-1}} = \prod_{l=0}^{k-1} g^{f_l \cdot j^l} = \prod_{l=0}^{k-1} F_j^{j^l}$$

Threshold ElGamal

The threshold ElGamal [16] works as follows: At the beginning, n parties $(P_1, P_2, \ldots, P_n)$ need to agree on the ElGamal parameters (p, q, g). Recall that p and q are large primes, where $q|p-1$, and g is a generator of G_q. Then they work together to implement the following processes:

1. P_i randomly chooses $x_i \in Z_q$ and computes $y_i = g^{x_i}$.
2. The public key y is computed as $y = \prod_{i=1}^{n} y_i$.
   Now all parties know the public key y, but they cannot find the corresponding secret key $x = \sum_{i=1}^{n} x_i \pmod q$ unless they all work together. The next step is to learn how to distribute x to all parties in a verifiable way that any subset of k parties can recover it.
3. P_i randomly chooses a polynomial $f_i(z) \in Z_q(z)$ of degree at most $k-1$ such that $f_i(0) = x_i$. Let
   $$f_i(z) = f_{(i,0)} + f_{(i,1)} z + \cdots + f_{(i,k-1)} z^{k-1}$$
   where $f_{(i,0)} = x_i$.
4. P_i computes $F_{(i,j)} = g^{f_{(i,j)}}$ for $j = 0, 1, \ldots, k-1$ and broadcasts $(F_{(i,j)})_{j=1,2,\ldots,k-1}$. (Note that $F_{(i,0)} = y_i$ is known beforehand.)
5. After every party broadcasts the $k-1$ values in the previous step, P_i sends $s_{ij} = f_i(j)$ and a signature secretly to every other party P_j where $j = 1, 2, \ldots, n$. (Note that in particular, P_i keeps s_{ii}.)
6. P_i verifies that the share s_{ji} received from P_j is consistent with the previously published values by verifying that
   $$g^{s_{ji}} = \prod_{l=0}^{k-1} F_{(j,l)}^{i^l}$$
   This is because
   $$g^{s_{ji}} = g^{f_{(j,0)} + f_{(j,1)} i + \cdots + f_{(j,k-1)} i^{k-1}} = \prod_{l=0}^{k-1} g^{f_{(j,l)} i^l} = \prod_{l=0}^{k-1} F_{(j,l)}^{i^l}$$
   If this check fails, P_i broadcasts that an error has been found, publishes s_{ji} and the signature, and then stops.
   - P_i computes her share of the secret key as the sum of all shares received in step 5 as
   $$s_i = \sum_{j=1}^{n} s_{ji} \pmod q$$

As follows, P_i signs the public key y. Finally, after all parties have signed y, anyone can check whether y is agreed among all these parties.

Zero-Knowledge Proofs

A zero-knowledge proof allows the prover to demonstrate some fact to the verifier without revealing the secret details of the fact. According to the definitions in '*Handbook of Applied Cryptography*'[17], it should achieve the following three properties:

- **Completeness:** Given an honest prover and an honest verifier, the protocol will succeed with overwhelming probability. The definition of "overwhelming" depends

on the application, but generally implies that the probability of failure is not of practical significance.

- **Soundness:** If there exists an expected polynomial-time algorithm with the following property—if a dishonest prover can with nonnegligible probability successfully execute the protocol with the honest verifier—then the same algorithm can be used to extract some knowledge which is essentially equivalent to the honest prover's secret.
- **Zero-knowledge:** There exists an expected polynomial-time algorithm that can produce, upon input of the assertion to be proven but without interacting with the real prover, transcripts indistinguishable from those resulting from interaction with the real prover.

Interactive Proofs and Fiat-Shamir Heuristics

Generally speaking, an interactive zero-knowledge proof works as follows[5]:

- The prover sends a *witness* to the verifier. The witness works as a commitment in the protocol.
- The verifier sends a *challenge* back to the prover. The challenge could be the outcome of fair coin toss.
- The prover sends a *response* to the verifier. The calculation of the response needs to take into account the witness, the challenge, and the secret.

In the interactive zero-knowledge proof, both the prover and the verifier need to be present during the execution of the protocol. Sometimes, it will be more convenient if the prover can generate a transcript of the protocol so that the verifier can verify it at some later time. By using the Fiat-Shamir heuristic [18], this can be achieved by transferring an interactive proof into a noninteractive proof. The noninteractive zero-knowledge proof (NIZKP) normally works as follows:

- The prover generates a *witness*.
- The prover takes the witness as well as some other necessary information as inputs, and outputs the *challenge* using some hash function.
- The prover calculates the *response* and then sends the transcript, which includes the witness, the challenge, and the response to the verifier.

The security of NIZKP, which can be proved using the *Random Oracle Model* [19], is based on the fact that the verifier cannot predict the outcome of the hash function. Otherwise, she can fabricate a proof that will be accepted by the verifier.

5. Here, we only illustrate the technique using examples of three-round interactive proofs. Some proofs may have more rounds, but their concept is similar.

In the following paragraphs, we describe several zero-knowledge proofs in the interactive form. They can be transferred into noninteractive zero-knowledge proofs similarly using the Fiat-Shamir heuristics.

Schnorr Identification Algorithm

The Schnorr Identification Algorithm [20] is widely used to prove knowledge of the ElGamal secret key without revealing it. The basic theory is as follows: Suppose p, q are two large primes where $q|p-1$. Let g be a generator of group G_q, which is a subgroup of Z_p^*. Suppose $x \in Z_q$ is the secret key and $y = g^x$ is the corresponding public key. The prover ***P*** can prove that she knows x without disclosing it to the verifier ***V***.

- ***P*** randomly chooses a value $c \in Z_q$ and sends $w = g^c$ to ***V***.
- ***V*** sends a random challenge $e \in Z_q$ back to ***P***.
- ***P*** calculates $s = c + xe \pmod{q}$, and sends s to ***V***.
- ***V*** checks $g^s = wy^e$.

Moreover, for an ElGamal ciphertext $(G, M) = (my^r, g^r)$, the Schnorr Identification Algorithm also can be used to prove knowledge of its plaintext m without revealing it. The protocol first proves that ***P*** knows the blinding factor r in g^r. Because y is a public parameter, if ***P*** knows r, she can retrieve m by calculating $m = G/y^r$. Therefore, the protocol also proves that ***P*** knows the plaintext m.

Chaum-Pedersen Protocol

The Chaum-Pedersen protocol [21] is used to prove the equality of discrete logarithm. Suppose (g, y) is the ElGamal public key pair and the secret key is $x = log_g y$. By using the Chaum-Pedersen protocol, the prover ***P*** can prove to the verifier V that a pair (m, n) achieves the following property: $log_g y = log_m n = x$. We denote such a proof as ***CP*** (g,y,m,n).

- ***P*** randomly chooses a value $c \in Z_q$; then he sends $U = g^c$ and $V = m^c$ to ***V***.
- ***V*** sends a random challenge $e \in Z_q$ back to ***P***.
- ***P*** calculates $s = c + xe \pmod{q}$ and sends s to ***V***.
- ***V*** checks $g^s = Uy^e$ and $m^s = Vn^e$.

The Chaum-Pedersen protocol also can be used to prove that an ElGamal ciphertext $(G', M') = (Gy^s, Mg^s)$ is a re-encryption of $(G, M) = (my^r, g^r)$ without revealing the randomization factor s. The proof is, ***CP***$(y, G'/G, g, M'/M)$ which implies that there exists a value s such that $log_y(G'/G) = log_g(M'/M)$. Moreover, the Chaum-Pedersen protocol can be used to prove that an ElGamal ciphertext has been correctly decrypted.

Cramer-Damgård-Schoenmakers Protocol

The witness hiding/indistinguishable protocol was introduced by Cramer, Damgård, and Schoenmakers in [22]; therefore it is also known as the CDS protocol. It can be used to prove that a party knows the solution of k out of n problems without revealing which problems she can solve. This protocol is normally used in verifiable voting schemes to prove that a ciphertext is an encryption of one value within a subset of different values. Here, we only introduce the basic theory of the CDS protocol; for its technical details, please refer to [22].

For example, there exists n different questions $Q_1, Q_2, \ldots, Q_n$. The prover ***P*** wants to prove to the verifier ***V*** that she knows the solution of one question. But ***P*** does not want ***V*** to find out which solution she knows. ***P*** can execute the CDS protocol with ***V*** as follow:

- Suppose ***P*** knows the solution δ_i of the i-th question Q_i, ***P*** first randomly selects r_i and calculates the genuine witness t_i. ***P*** then randomly chooses fake challenges c_j, fake responses s_j and uses them to fabricate the witnesses t_j, where $j \neq i$. ***P*** sends all these witnesses $(t_1, t_2, \ldots, t_n)$ to ***V***.
- ***V*** randomly selects a challenge c^* and sends it to ***P***.
- ***P*** calculates $c_i = c^* - \sum_{j \neq i} c_j$. Then she calculates the real response s_i, using r_i, c_i and her knowledge δ_i. After that, ***P*** sends $(c_1, c_2, \ldots, c_n)$ and $(s_1, s_2, \ldots, s_n)$ to ***V***.
- ***V*** checks that $c^* = \sum_{k=1}^{n} c_k$ and for all the questions, each of their proofs is satisfied. However, ***V*** will be unable to distinguish the real proof from the fake proofs.

Mixnets

A mixnet is a cryptographic building block implemented by a number of mix servers. It takes a list of encrypted values as input, and it outputs a list of values (encrypted or decrypted depending on the type of mixnet) corresponding to the input list, but permuted so that the links between individual inputs and outputs are hidden. When the mixnet receives a number of encrypted values as inputs, each mix server will either partially decrypt (in a decryption mix) or re-encrypt (in a re-encryption mix) each of the encrypted values and output the results to the next mix server in a permuted order. Therefore, if there exists at least one honest mix server, the relationships between the mixnet inputs and outputs will be kept private. However, the main challenge is how to efficiently prove that the mixnet has generated the correct outputs without revealing the input and output relationships.

In the literature, there are two types of mixnets: *decryption mixnets* and *re-encryption mixnets*. Their difference is that in decryption mixnets, each mix server will partially decrypt the received encrypted list and the final mixnets outputs are plaintext values. But in re-encryption mixnets, each mix server re-encrypts the received encrypted list, and the final mixnets outputs are still encrypted values. In general, re-encryption mixnets are more robust and versatile because their re-encryption phase and the decryption phase are separated. And the mix servers only need public information to carry out the re-encryption phase.

Moreover, there are also two types of methods to verify the correctness of mixnets: *cut-and-choose* and *efficient proofs*. The cut-and-choose method can be used in both decryption mixnets and re-encryption mixnets. For example, we can randomly require half of the links of the mixnet to be opened in order to check whether the partial decryption or re-encryption is done properly. However, the challenge is how to design an architecture so that the opened links still do not reveal the relationships between inputs and outputs—that is, there are no chains of opened links that relate inputs to outputs. Another issue is that if only one value is altered within the mixnets,[6] a single round of the cut-and-choose method only gives 50 percent probability to detect the cheating. To increase the probability of detecting such cheating, we need to run the audit a number of times, but this will make the verification process expensive. Efficient proofs are more complex, and they mainly work for re-encryption mixnets. Each mix server generates a transcript proof for the shuffle she has done. The proof proves that no value is added, removed, or altered during the shuffle, and it can be publicly verified. Otherwise, even if a single value is altered, the proof will fail with overwhelming probability.

In the following paragraphs, we briefly describe two mixnet examples: one decryption mixnet verified using the cut-and-choose method, and one re-encryption mixnet verified using the efficient proofs.

Chaum's Mixnet and Randomized Partial Checking

Chaum's mixnet [23] works as follows: Suppose $\{(K_1, K_1^{-1}), (K_2, K_2^{-1}), \ldots, (K_m, K_m^{-1})\}$ are a number of key pairs, where K_i is the public key and K_i^{-1} is the corresponding secret key (for $i = 1, 2, \ldots, m$). The public keys are all made public, and each secret key is held by an individual mix server. The mixnet inputs are a list of ciphertexts $L_0 = (l_{01}, l_{02}, \ldots l_{0n})$, where the i-th ciphertext is

$$l_{0i} = K_1(K_2(\ldots(K_{m-1}(K_m(m_i, r_m), r_{m-1})\ldots), r_2), r_1)$$

This ciphertext is commonly known as an *onion* due to its layered structure. When receiving the mixnet inputs, the first mix server will use her secret key K_1^{-1} to decrypt each of the onions in L_0, and she then removes the randomization

6. Normally, this attack does not aim to dramatically change the election result, but rather to find out how a voter has voted.

values, shuffles the remaining values, and outputs the result list L_1 onto the WBB. At this moment, there should be a value $K_2(\ldots(K_{m-1}(K_m(m_i, r_m), r_{m-1})\ldots), r_2)$ in the list L_1. But because of the shuffle, its index will be changed. As follows, the next mix server downloads the list L_1 from the WBB, decrypts each of the ciphertext using her secret key K_2^{-1}, removes the randomization values, shuffles the remaining values, and outputs the result list L_2 to the WBB. This process is continued until the ciphertext list is decrypted by all the mix servers. Finally, the last mix server will output the list L_m, which contains all the plaintexts.

Chaum's mixnet can be verified using Randomized Partial Checking (RPC) [24]. To enable this, the mixnet needs to be implemented in a slightly different way. Each mix server needs to implement two shuffles, and every two adjacent mix servers are paired together, as shown in Figure 69.1. To audit the mixnet, each pair of the mix servers is verified separately as follows:

1. For the left mix server, the auditor will go down the middle column and randomly assign half units L and the other half units R.
2. For units assigned L, the auditor requires the left mix server to reveal the corresponding links in her first shuffle (incoming links).
3. For units assigned R, the auditor requires the left mix server to reveal the corresponding links in her second shuffle (outgoing links).
4. For the right mix server, for exactly half of the inputs she receives, their incoming links have already been revealed. We denote that these units are in the group G_1 and the other units are in the group G_2. Then the auditor randomly assigns half units in G_1 and half units in G_2 and requires the right mix server to reveal their outgoing links.
5. In the last shuffle, for the units whose incoming links have not been revealed, the right mix server is required to reveal their outgoing links.

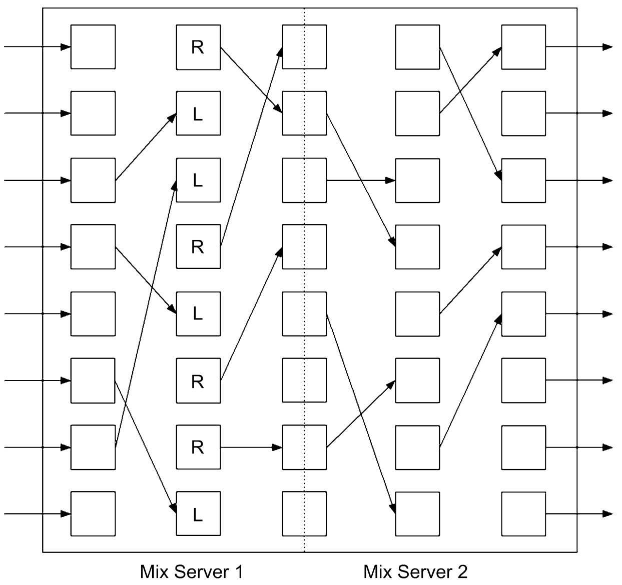

FIGURE 69.1 Randomized partial checking.

To open a link, the mix server needs to reveal either the source of the link (for incoming links) or the destination of the link (for outgoing links) as well as the randomization value. Therefore, the auditor who has access to the public key can recalculate the link using the revealed information. Thanks to the above architecture, although half of the links have been audited, the remaining links still ensure that the inputs and outputs relationships are kept private if there exists at least one pair of honest mix servers. In other words, a mixnet input can be output at any index with equal probability.

Neff's Mixnet

Neff's mixnet [25,26] works as follows: The original inputs for the mixnet are a list of ElGamal ciphertexts, and each ciphertext is accompanied by a zero-knowledge proof to prove the knowledge of its plaintext.[7] Before the shuffle starts, any input with an invalid proof will be removed, and this process can be publicly verified. After that, the first mix server downloads the remaining ciphertexts from the WBB (ignores their proofs), re-encrypts each of the ciphertexts, and outputs the results to the WBB in a random order. Moreover, the mix server also generates an efficient proof to prove that the re-encryption is correctly performed without revealing the shuffle. Such a proof is also published on the WBB. Then the following mix servers will implement exactly the same processes in sequence. Finally, the mixnet outputs are published onto the WBB by the last mix server.

The key contribution of Neff's mixnet is to demonstrate how to construct an efficient proof. Here, we review the basic ideas. For more technical details, the readers are referred to [25,26].

Iterated Logarithmic Multiplication Proof Protocol (ILMPP): Suppose the vectors $\{X_i\}_{i=1}^k$ and $\{Y_i\}_{i=1}^k$ are publicly known, where $x_i = log_g X_i$ and $y_i = log_g Y_i$ are only known to the prover ***P***. Then ***P*** can use ILMPP to prove to the verifier ***V*** that $\prod_{i=1}^k x_i = \prod_{i=1}^k y_i$ without revealing any of the x_i and y_i.

The Simple *k*-Shuffle: Suppose the vectors $\{X_i\}_{i=1}^k$ and $\{Y_i\}_{i=1}^k$ are publicly known, where $x_i = log_g X_i$ and $y_i = log_g Y_i$ are only known to the prover ***P***. In addition, constants $c \in Z_q$ and $d \in Z_q$ are only known to ***P***, and their commitments $C = g^c$ and $D = g^d$ are made public.

7. The proof prevents the adversary from submitting a ciphertext that is related to another ciphertext by an honest party. Otherwise, the adversary may use this attack to find out the honest party's plaintext.

Then ***P*** can prove to the verifier ***V*** that $Y_i^d = X_{\pi(i)}^c$ for some permutation π, without revealing any of the value x_i, y_i, c, d and π. Note that P actually proves that $y_i/c = x_{\pi(i)}/d$ for $i = 1, 2, \ldots, k$. The protocol works as follows:

- ***V*** generates a random challenge $t \in Z_q$ and sends it to ***P***.
- ***P*** and ***V*** publicly compute $U = D^t = g^{dt}$ and $W = C^t = g^{ct}$.
- Then, for the public inputs

$$(X_1/U, X_2/U, \ldots, X_k/U, \overbrace{C, C, \ldots, C}^{k})$$

and

$$(Y_1/W, Y_2/W, \ldots, Y_k/W, \overbrace{D, D, \ldots, D}^{k})$$

- P can use the ILMPP as a subprotocol to prove to ***V*** that $c^k \times \prod_{i=1}^k (x_i - dt) = d^k \times \prod_{i=1}^k (y_i - ct)$.

Note that if we divide $(cd)^k$ at both sides of the above equation, the equation can be rewritten as:

$$\prod_{i=1}^{k} (x_i/d - t) = \prod_{i=1}^{k} (y_i/c - t)$$

Therefore, because t is a random value chosen by ***V***, ***P*** actually proves that for some permutation π and $i = 1, 2, \ldots, k$, we have $y_i/c = x_{\pi(i)}/d$.

ElGamal Shuffle: In a mixnet, if the mix server ***M*** is honest, for any output j and some permutation π, we should always have

$$(\alpha_{j'}, \beta_{j'}) = (g^{r_{\pi(j)}} \alpha_{\pi(j)}, y^{r_{\pi(j)}} \beta_{\pi(j)})$$

To prove the shuffle is correctly performed, ***M*** first publishes a commitment C and a random vector $\{T_j\}_{i=1}^k$, where $c = log_g C$ and $t_i = log_g T_j$. Then ***M*** can generate $U_j = T_{\pi(j)}^c$ and prove that this is correctly performed using the simple k-shuffle as a subprotocol.[8] Finally, ***M*** just demonstrates the knowledge of $\Delta = \sum_{j=1}^k r_j t_j$ such that

$$log_g \frac{\prod_{j=1}^{k} (\alpha_{j'})^{u_i}}{\prod_{j=1}^{k} \alpha_j^{t_i c}} = log_y \frac{\prod_{j=1}^{k} (\beta_{j'})^{u_i}}{\prod_{j=1}^{k} \beta_j^{t_i c}} = \Delta c$$

If the above equation holds, it proves two facts: first, the same randomization value has been used to re-encrypt both α_j and β_j. And second, because

$$\sum_{j=1}^{k} r_{\pi(j)} t_{\pi(j)} c = \Delta c = \sum_{j=1}^{k} r_j t_j c$$

it proves that the same permutation π has been used both in the simple k-shuffle and the ElGamal shuffle.

8. Note that $d = 1$ in this case.

Other Useful Techniques

Some other techniques are also sometimes used in designing verifiable voting schemes. Here we review four of them. The *blind signature* allows the signer to sign a message without learning the message content. The *designated verifier proof* is used to prove some fact to a designated verifier, but the verifier cannot transfer the proof to others. The *plaintext equivalence test* can test whether two ciphertexts are containing the same plaintext without revealing the plaintext. *Proxy re-encryption* is used to transfer a ciphertext encrypted under one public key to a ciphertext encrypted under another public key, where the two ciphertexts contain the same plaintext.

Blind Signature

Blind signature [27] is a kind of digital signature in which the message is blinded before it is signed. Therefore, the signer will not learn the message content. Then the signed message will be unblinded. At this moment, it is similar to a normal digital signature, and it can be publicly checked against the original message. Blind signature can be implemented using a number of public-key encryption schemes. Here, we only introduce the simplest one, which is based on RSA encryption. The signer has a public key (n, e) and a secret key d. Suppose a party A wants to have a message m signed using the blind signature. She should execute the protocol with the signer S as follows:

- A first randomly chooses a value k, which satisfies $0 \le k \le n - 1$ and $gcd(n, k) = 1$.
- For the message m, A computes $m^* = mk^e \pmod n$ and sends m^* to S.
- When S receives m^*, S computes $s^* = (m^*)^d \pmod n$ and sends s^* back to A.
- A computes $s = s^*/k \pmod n$. Now s is S 's signature on the message m.

Designated Verifier Proof

Designated verifier proof (DVP) [28] can be used to prove some fact (e.g., an ElGamal re-encryption is performed correctly) to a designated verifier in a way that the proof cannot be transferred to others.

Let (p, q, g) be the ElGamal parameters. Suppose s_v is the secret key of the verifier V, and the corresponding public key is $y_v = g^{s_v}$. Let $(G, M) = (my^\alpha, g^\alpha)$ be the original message, and $(G', M') = (Gy^\beta, Mg^\beta)$ be a re-encrypted message generated by the prover ***P***. ***P*** can prove to ***V*** using DVP that the re-encryption is executed properly, but ***V*** cannot use the same proof to convince others about this fact. The key point of the proof is to prove that G'/G and M'/M have the same discrete logarithm β under the

bases g and y, respectively. A noninteractive proof of the DVP is as follows:

- ***P*** chooses $k, r, t \in_R Z_q$.
- ***P*** computes $(a, b) = (g^k, y^k)$ and $d = g^r {y_v}^t$.
- ***P*** computes $c = H(a, b, d, G', M')$ and $u = k - \beta(c + r) \pmod q$.
- ***P*** sends (c, r, t, u) to V.
- ***V*** verifies $c = H(g^u(M'/M)^{c+r}, y^u(G'/G)^{c+r}, g^r {y_v}^t, G', M')$.

If ***P*** has re-encrypted correctly, the honest ***V*** will always accept the proof because:

$$a = g^k = g^{u+\beta(c+r)} = g^u g^{\beta(c+r)} = g^u(M'/M)^{c+r}$$
$$b = y^k = y^{u+\beta(c+r)} = y^u y^{\beta(c+r)} = y^u(G'/G)^{c+r}$$

Therefore

$$c = H(a, b, d, G', M') = H(g^u(M'/M)^{c+r}, y^u(G'/G)^{c+r}, g^r {y_v}^t, G', M')$$

In this protocol, $d = g^r {y_v}^t$ is a trapdoor commitment. If ***P*** does not know the secret key s_v, then t and r have been properly committed and ***P*** has to calculate u to ensure the proof will be accepted by ***V***. Since ***P*** knows β, she can find out such u. But because ***V*** knows the secret key s_v, she can reform $d = g^r {y_v}^t$ as $d = g^r \cdot g^{s_v t} = g^{r+s_v t}$, ***V*** is able to generate a fake proof for any $(\overline{G}, \overline{M}) = (m'y^\theta, g^\theta)$ that $(G', M') = (my^{\alpha+\beta}, g^{\alpha+\beta})$ is the re-encryption of $(\overline{G}, \overline{M})$. This is because ***V*** can generate any pair $(\overline{r}, \overline{t})$, where $r + s_v t \equiv \overline{r} + s_v \overline{t} \pmod q$. In this case, ***V*** can work as the prover to fabricate a proof. She first selects $(\overline{\gamma}, \overline{\delta}, \overline{u})$ and computes

$$\overline{c} = H(g^{\overline{u}}(M'/\overline{M})^{\overline{\gamma}}, y^{\overline{u}}(G'/\overline{G})^{\overline{\gamma}}, g^{\overline{\delta}}, G', M')$$

Then ***V*** computes $\overline{r}$ as $\overline{r} = \overline{\gamma} - \overline{c} \pmod q$, and $\overline{t}$ to satisfy $\overline{\delta} = s_v \overline{t} + \overline{r} \pmod q$. As a result, the verifier will accept $(\overline{c}, \overline{r}, \overline{t}, \overline{u})$ as the proof because

$$\overline{a} = g^{\overline{u}}(M'/\overline{M})^{\overline{c}+\overline{r}} = g^{\overline{u}}(M'/\overline{M})^{\overline{\gamma}}$$
$$\overline{b} = y^{\overline{u}}(G'/\overline{G})^{\overline{c}+\overline{r}} = y^{\overline{u}}(G'/\overline{G})^{\overline{\gamma}}$$
$$\overline{d} = g^{\overline{r}} {y_v}^{\overline{t}} = g^{\overline{r}+s_v\overline{t}} = g^{\overline{\delta}}$$

Therefore

$$\overline{c} = H(\overline{a}, \overline{b}, \overline{d}, G', M') = H(g^{\overline{u}}(M'/\overline{M})^{\overline{\gamma}}, y^{\overline{u}}(G'/\overline{G})^{\overline{\gamma}}, g^{\overline{\delta}}, G', M')$$

Plaintext Equivalent Test

Suppose (G_1, M_1) and (G_2, M_2) are two ElGamal ciphertexts encrypted under the same public key, where the private key is threshold shared among a set of parties. The plaintext equivalent test (PET) [29] is a function to check whether the two ciphertexts contain the same plaintext, without revealing it. Denote $(\varepsilon, \zeta) = (G_1/G_2, M_1/M_2)$; therefore, if and only if the two ciphertexts contain the same plaintext, (ε, ζ) will represent an encryption of the plaintext integer 1. Each party P_j randomly selects $z_j \in Z_q$ and commits it using the Pedersen commitment [30]. Then P_j published $(\varepsilon_j, \zeta_j) = (\varepsilon^{z_j}, \zeta^{z_j})$ with the Chaum-Pedersen proof that (ε_j, ζ_j) is well formed. As follows, all parties jointly decrypt $(\gamma, \delta) = (\prod_{j=1}^n \varepsilon_j, \prod_{j=1}^n \zeta_j)$. If and only if the result plaintext is 1, the two ciphertexts (G_1, M_1) and (G_2, M_2) will contain the same plaintext.

Proxy Re-encryption

A proxy re-encryption [31] is a function to transfer an ElGamal encryption from one encryption key to another encryption key. Let $(G_1, M_1) = (m \cdot y_1^r, g^r)$ be an ElGamal encryption of a plaintext m using public key y_1, and let x_1 be the corresponding secret key, which is shared among a number of parties using a threshold scheme. A quorum Q of these parties can transfer (G_1, M_1) to an ElGamal encryption (G_2, M_2), which contains the same plaintext with respect to the public key y_2, without revealing m. First, P_j selects a value δ_j uniformly at random from Z_q, and computes $(\alpha_j, \beta_j) = (M_1^{-x_{1j}L_j} {y_2}^{\delta_j}, g^{\delta_j})$. Here x_{1j} is P_j's share of the secret key and $L_j = \prod_{i \in Q} \frac{i}{i-j}$. Then (G_2, M_2) can be computed as $(G_2, M_2) = (G_1 \prod_{j \in Q} \alpha_j, \prod_{j \in Q} \beta_j)$.

5. SURVEY OF NOTEWORTHY SCHEMES

In this section, we review a number of noteworthy verifiable voting schemes. Our purpose is not to cover every scheme in the literature, but to divide the existing schemes into several categories; we briefly describe one or two typical schemes in each category. Hopefully, this will give the readers an overview of various research works in developing verifiable voting schemes.

Schemes Based on Blind Signature

Schemes based on blind signature were first introduced by Fujioka, Okamoto, and Ohta in [32], which is normally called the FOO scheme. Although several later papers [33–36] have introduced various further improvements to the FOO scheme, their election procedures are similar, and the FOO scheme is still widely regarded as the milestone in this category.

The FOO scheme works as follows: The involved parties are the voters, the administrator, the counter, and the WBB. At first, a certain voter selects her choice v, encrypting it by bit-commitment $\{v\}_k$ and then by blind signature $\{\{v\}_k\}_{blind}$. After that, she sends it to an administrator. The administrator will only sign the ballot if this voter is eligible and has not applied the signature before. When the voter receives the signed ballot $\{\{\{v\}_k\}_{blind}\}_{sign}$ from the administrator, she will unblind it $\{\{v\}_k\}_{sign}$ and send it to the counter through an anonymous channel. Normally, the anonymous channel is implemented by

mixnets. As follows, the counter checks whether the ballot contains the administrator's signature. If yes, the counter will put it onto the WBB. Otherwise, she will reject this ballot. Now, the voter can verify whether her vote $\{v\}_k$ is correctly displayed on the WBB. If not, she can complain to a trusted party. Otherwise, she will send her de-commitment key k to the counter anonymously after some designated time T. Finally, the counter decrypts each ballot v and publishes them on the WBB.

Schemes based on blind signature ensure voter privacy and allow voters to verify that their votes are received by the election system. Furthermore, the fairness property is guaranteed so that no early result can be revealed before the designated time T. However, they also suffer several drawbacks. One issue is that messages must be sent to the election authorities twice, which means that voters have to be involved during the whole election procedures. Another issue is that voter privacy will be violated if a voter discovers an incorrectly recorded receipt and complains to the authority. Moreover, if there exists some mixnet for the anonymous channel, then the blind signature technique is no longer needed to design verifiable voting schemes. Because of these issues, blind signature schemes have not attracted much recent interest.

Schemes Based on Mixnets

Note that the schemes based on mixnets discussed here are early schemes which assume that voters are able to generate their encrypted votes as well as the necessary proofs. So they only focus on the tally phase. Many later voter-verifiable schemes also employ mixnets as building blocks, but they concentrate on a different problem: how to allow ordinary voters to cast their encrypted votes without special knowledge.

Schemes based on mixnets have been developed along with the mixnets. In the first mixnet protocol [23], Chaum suggested that the mixnet can be used in voting schemes to provide voter privacy. And later, many mixnet protocols have used voting as an example of their application. Here, we describe the scheme introduced by Sako and Kilian in [37], and many other schemes share similar ideas.

At first, each voter generates an encrypted vote $(\alpha_i, \beta_i) = (m_i \cdot y^r, g^r)$ that contains her choice m_i. The voter also generates an Σ-proof (e.g., using the Schnorr Identification Algorithm) that she knows m_i without revealing it. Then she publishes (α_i, β_i) as well as the Σ-proof onto the WBB. After receiving all the encrypted votes from every voter, a set of mix servers will re-encrypt and shuffle these votes in sequence. Finally, the mixnet outputs will be decrypted in a threshold fashion.

For a particular mix server, suppose the list $L_{in} = \{(\alpha_1, \beta_1), \ldots, (\alpha_n, \beta_n)\}$ is her inputs and the list $L_{out} = \{(\alpha_{\pi(1)}', \beta_{\pi(1)}'), \ldots, (\alpha_{\pi(n)}', \beta_{\pi(n)}')\}$ is her outputs. To audit this mix server, she is required to generate another list $L_{mid} = \{(\alpha_{\sigma(1)}'', \beta_{\sigma(1)}''), \ldots, (\alpha_{\sigma(n)}'', \beta_{\sigma(n)}'')\}$, which is also the re-encryption and shuffle of the list L_{in}. Then the verifier can flip a coin. If heads, the mix server needs to reveal σ and all the necessary randomization values to prove that L_{mid} is a shuffle of L_{in}. Otherwise, if tails, the mix server will reveal $\pi \circ \sigma^{-1}$ and all the necessary randomization values to prove that L_{out} is a shuffle of L_{mid}. It is clear that such an audit will not reveal the permutation π, and it gives 50% probability of detecting cheating if one vote has been altered during the shuffle. Moreover, the audit can be repeated for several rounds (each round with an independently generated L_{mid}) to increase the probability of detecting cheating. Hence it can be verified that no vote has been added, altered, or removed within the mixnet.

To design a verifiable voting scheme based on mixnet, another challenge is how to verify that all the mixnet outputs have been correctly decrypted. Normally, the secret key x is shared among a number of tellers in a threshold fashion; and ciphertexts are threshold decrypted by a quorum of tellers.

Schemes Based on Homomorphic Encryption

Schemes based on homomorphic encryption were first introduced by Josh Benaloh in [38–40]. Later, several improved schemes (e.g., [41–45]) were developed. These schemes follow similar election procedures, but they introduce new security properties, such as the receipt-freeness, and they use more efficient building blocks to replace those in Benaloh's schemes. Here, we review a recent scheme introduced by Baudron et al. in [41].

Suppose the maximum number of voters is M and there are k candidates. Those candidates will be assigned the values $\{M^0, M^1, \ldots, M^{k-1}\}$, respectively. Suppose also that a voter wants to vote for the i-th candidate. She first generates a Paillier ciphertext, which encodes M^{i-1} as well as a proof that her ciphertext is valid. The proof is generated using the witness hiding protocol (the CDS protocol), and it proves that her plaintext is within the set $\{M^0, M^1, \ldots, M^{k-1}\}$ without revealing which one it is. Then she submits both the encrypted vote and the proof to the WBB. When the election closes, any vote with invalid proof will be removed from the tally. As follows, the remaining encrypted votes will be multiplied together into a single ciphertext. Thanks to the additive homomorphic property, this single ciphertext will encode a value, R which is the sum of each individual plaintext. Moreover, the R value can be considered to contain a set of counters $\{M^0, M^1, \ldots, M^{k-1}\}$, and each counter records how many votes have been received for the corresponding candidate. For example, if a voter votes for the i-th candidate, when her encrypted vote is aggregated into the single ciphertext, the counter M^{i-1} will add one. Note that

the ciphertext aggregation does not require any secret information, so anyone can check whether it is done correctly by performing the calculation again. Finally, the single ciphertext is decrypted in a threshold fashion, and the value R is revealed. At this moment, if R is divided by M^{k-1}, the result is the number of votes received by the k-th candidate. If the remainder of the previous calculation is divided by M^{k-2}, we get the number of votes received by the $(k-1)$-th candidate, and so on.

Compared with schemes based on mixnets, schemes based on homomorphic encryption are much simpler in the tallying phase. However, voters' tasks are more substantial because the witness hiding proof is more complex than the Schnorr Identification proof. Moreover, they are not as versatile as the schemes based on mixnets since they lack the ability to handle information-rich elections such as Single Transferable Vote (STV) elections. Schemes based on mixnets and homomorphic encryption have received much recent interest in the literature.

Specific Voter-Verifiable Schemes

In voter-verifiable schemes, voters are not assumed to have special knowledge to generate their votes as well as to do any necessary proofs themselves. Instead, some novel techniques can help them to generate their verifiable votes, and they can verify that their votes correctly encode their intent. We review three noteworthy schemes in this category: the MarkPledge scheme by Neff [46], a scheme using visual cryptography by Chaum [47], and Scantegrity II [48].

MarkPledge: Suppose there are n candidates $\{C_1, C_2, \ldots, C_n\}$ and κ is a security parameter. The MarkPledge scheme works as follows:

- An authenticated voter in the voting booth will be allowed to use the voting machine. This voter tells her choice C_i to the voting machine, and meanwhile, she gives $n-1$ challenges $\{c_j\}_{j\neq i}$ to the voting machine, where each challenge is a κ bits binary. These challenges are supposed to be generated uniformly random, but if a voter is coerced to vote for the k-th candidate C_k, he can use the value given by the coercer to replace c_k.
- The voting machine generates this voter's ballot, which can be illustrated as follows:

$$\begin{array}{cccccc} & 1 & 2 & 3 & & k \\ C_1 & \boxed{0}\boxed{1} & \boxed{1}\boxed{0} & \boxed{0}\boxed{1} & \cdots & \boxed{1}\boxed{0} \\ C_2 & \boxed{0}\boxed{1} & \boxed{0}\boxed{1} & \boxed{1}\boxed{0} & \cdots & \boxed{1}\boxed{0} \\ & \cdots & \cdots & \cdots & \cdots & \cdots \\ C_i & \boxed{1}\boxed{1} & \boxed{1}\boxed{1} & \boxed{0}\boxed{0} & \cdots & \boxed{1}\boxed{1} \\ & \cdots & \cdots & \cdots & \cdots & \cdots \\ C_n & \boxed{1}\boxed{0} & \boxed{0}\boxed{1} & \boxed{0}\boxed{1} & \cdots & \boxed{0}\boxed{1} \end{array}$$

Denote $\boxed{0}$ and $\boxed{1}$ as ElGamal ciphertexts with plaintexts 0 and 1, respectively. If the voting machine is honest, for the i-th candidate C_i, the voting machine generates κ pairs of ElGamal ciphertexts, where the plaintext is the same in each pair. But for all other candidates, it generates κ pairs of ElGamal ciphertexts, where the plaintext is different in each pair.

- For the ballot generated in the previous step, the voting machine commits all pledges on how each ElGamal ciphertext pair will be opened. Because for all candidates except the i-th one, the voting machine has already known how their ElGamal ciphertext pairs will be challenged, it can announce their pledges properly.
- The voter then sends the challenge c_i for the i-th candidate to the voting machine. c_i is also a κ bits binary.
- For all candidates, the voting machine reveals the ElGamal ciphertext pairs according to the challenge values. For example, for any candidate, if the t-th bit of the challenge is 0, the voting machine opens the left part in the t-th ElGamal ciphertext pair. Otherwise, it opens the right part.
- This voter, as well as any party who is interested, can verify whether all opened plaintexts match what the voting machine has committed (the pledges) in the third step.

Later, all the received votes will be tallied using mixnets. An attractive property of this scheme is that the voter does not need knowledge of cryptography to follow the election procedures. Later, whether the encrypted vote is correctly generated can be publicly checked via a cryptographic proof, and this will not reveal how the voter has voted. Moreover, adversaries are unable to coerce the voter to vote for a particular candidate. This is because the voter provides a real proof for her preferred candidate, and decoy proofs are provided for the other candidates; anyone who checks the proofs will not know which one is real.

If the voter follows the correct election procedures in the MarkPledge scheme, the encrypted vote not only can be cast but also can be used to verify that the voting machine is honest. For a dishonest voting machine, its cheating behavior can only go without being detected with probability $2^{-\kappa}$. However, if the voter does not understand the correct election procedures and reveals the challenge for her preferred candidate before the encrypted vote is constructed and how to open the ElGamal ciphertext pairs is pledged, the voting machine can cheat the voter by generating an encrypted vote for a different candidate. Moreover, the MarkPledge scheme lacks the ability to handle ranked elections, and the size of its encrypted votes is much larger compared with that of many other schemes.

Chaum's Visual Cryptography Scheme

To understand this scheme, some basic knowledge of *Visual Cryptography*[49] is necessary. There are two pixel symbols as shown in Figure 69.2. If we randomly choose one pixel symbol as the top layer and one pixel symbol as the bottom layer, and superimpose the two layers, the image can be illustrated in Figure 69.3. Thus, if the same pixel symbol occupies the same position in both layers, the image will be part-transparent. Otherwise, it will be opaque.

As shown in Figure 69.4, visual cryptography can be used to convey information if both layers are superimposed, but given either the top layer or the bottom layer, it contains no useful information. Chaum's visual cryptography scheme works as follows:

1. In the voting booth, an authenticated voter will be allowed to use the voting machine. She first reveals her choice to the voting machine.
2. The machine then prints a ballot image, similar to the one shown in Figure 69.4. In both layers, the information (θ_t, θ_b) is printed as well. If θ_t and θ_b are properly decrypted, they can be used to construct the pixel symbols in the top layer and bottom layer, respectively.
3. The voter checks whether the image contains her choice. If yes, she randomly chooses one layer to retain as her receipt, and the other layer needs to be destroyed.
4. Suppose this voter chooses to keep the top layer as her receipt. A copy of this layer will be published on the WBB as her encrypted vote. Later, the voter can check whether the vote in her receipt is displayed on the WBB.[9] If not, she can make a complaint to a trusted party using her receipt.

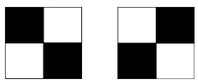

FIGURE 69.2 Two pixel symbols.

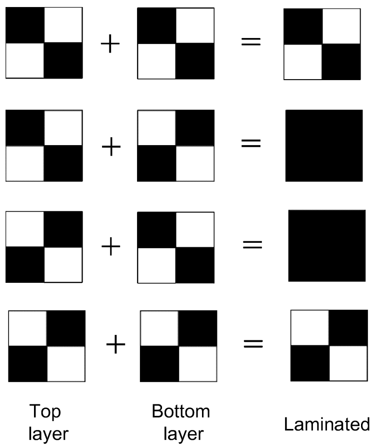

FIGURE 69.3 Two pixel symbols are laminated.

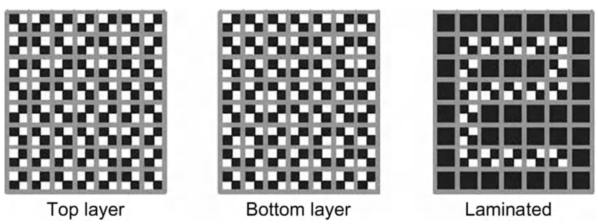

FIGURE 69.4 An application of visual cryptography.

To tally this vote, the pixel symbols in the top layer and θ_b will enable the election authorities to recover the vote choice. The tallying phase is done using Chaum's mix [23] and incorporating Randomized Partial Checking [24] to ensure that this phase is done properly.

Furthermore, the voter can use her receipt to check whether the ballot has been correctly generated by the voting machine. The voter first sends θ_t to the election authorities. Then they decode it and generate its corresponding pixel symbols. Finally, the voter compares the pixel symbols given by the election authorities and the ones printed on her receipt. As the retained layer is randomly chosen by the voter, this check gives the voter at least a 50 percent chance to detect the cheating if the voting machine is dishonest.

In Chaum's scheme, the voting procedures are straightforward, and it has the potential to handle various election methods (ranked elections). Later we will show that its user interface can be further improved using the Prêt à Voter style ballot forms.

Scantegrity II

This scheme [48] augments existing optical scan voting systems with voter verifiability. Optical scan systems are already in common use in the United States: Voters mark 'bubbles' on a paper ballot against their choices, and the ballot is read by an optical scanner and later tallied. The ballot forms are retained by the system.

Scantegrity II introduces a random secret code (a three-character code) with each bubble. The codes are fixed in advance and precommitted cryptographically so that they cannot be changed during or after the election. The code is revealed only when that bubble is marked. This is achieved using invisible ink for the code and special pens to mark the bubbles, such that the code is revealed. The voter makes a private note of the code and ballot serial number, and the ballot form is scanned and

9. Note that she should check that the pixel symbols, θ_t and θ_b are all matching.

retained as before. The codes received are published against the ballot serial numbers, and the voter can verify whether the published code matches her record. If it does not, then she can raise a challenge using her record of the code—a genuine code from the ballot form is considered as evidence of casting that vote, since it is extremely unlikely that a voter will guess a genuine code.

Voters can also audit ballot forms using cut-and-choose to check that the codes printed on them match the precommitted codes, by revealing all of the codes. Hence voters can check that ballot forms are correctly formed and verify that their vote has been captured and recorded correctly.

Non-crypto Schemes

Verifiable voting schemes also can be designed without using cryptography. Here we describe two interesting examples: One was introduced by Randell and Ryan in [50], and the other one is the ThreeBallot scheme by Rivest [51].

Randell and Ryan's Scheme

The Randell and Ryan scheme is a variant of the Prêt à Voter protocol (we will describe Prêt à Voter in more detail in the next section.). The ballot form, as shown in Figure 69.5, has a perforation down the middle. The left-hand side (LHS) lists the candidate names in a random order, and the candidate ordering varies in different ballots. At the bottom of the LHS, there is a unique *voter identification number* (VIN). The voter will use the RHS to mark her choice. At the bottom of the RHS is a number to record the *order of the candidate names* (OCN), but it is overprinted with a scratch strip, and the same VIN number is printed on top of the scratch strip.

In the polling station, an eligible voter will be given a random ballot. To prevent others from seeing the candidate ordering, each ballot can be distributed within an envelope. The voter takes the ballot into the voting booth, marks the choice against her preferred candidate, and separates the ballot along the perforation. Then she keeps the LHS as her receipt and submits the RHS without removing the scratch surface. Note that the election officials will only accept a ballot if its scratch surface is intact. Later, the VIN values for all the received ballots are published on the WBB. The voter can use her receipt to check whether her VIN number has been correctly recorded. To tally the votes, the election officials first remove the scratch surface of all received ballots. Then for each vote, its selected candidate can be retrieved using the position of the mark and the OCN value.

Apart from casting a ballot, the voter can also audit the ballot. The audit checks that the OCN value correctly represents the candidate ordering, and this will prevent a mark against one candidate being counted as a vote for another candidate. The voter can audit as many ballots as she likes, but she can only use an unaudited ballot to cast her vote. The reason is that once a ballot has been audited, its scratch surface will be removed.

The ThreeBallot scheme: A ballot form, as shown in Figure 69.6, consists of three parts that can be separated along the perforations between them. In each part, the candidate names are listed in the canonical order. But a unique value at the bottom of each part is different. To cast a vote, the voter should proceed row by row through

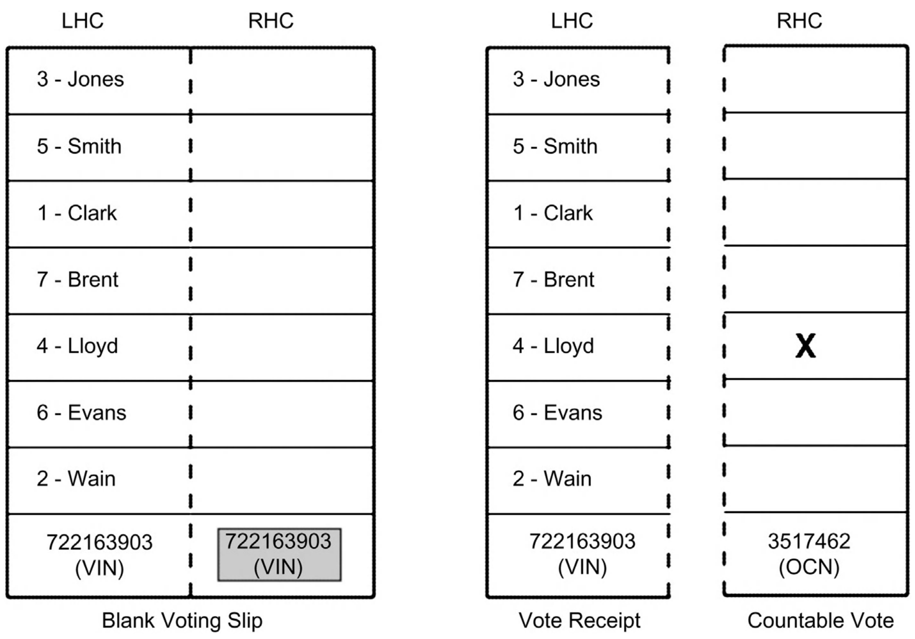

FIGURE 69.5 A ballot form example in the Randell and Ryan scheme.

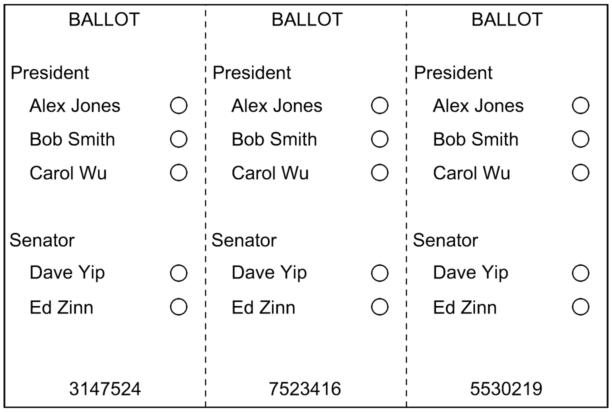

FIGURE 69.6 A ballot form example in the ThreeBallot scheme.

the ballot form. Each row corresponds to one candidate, and there are three bubbles in each row, one on each part. To vote for a candidate, the voter must fill in exactly two of the bubbles on that candidate row, and exactly one of the bubbles on all the other candidate rows. Then the voter inserts her ballot into some trusted machine that checks whether the ballot is correctly filled in. If yes, the machine prints some marks (e.g., a red line) on the ballot to prove it is valid. Otherwise, it will reject the ballot. Suppose the voter has filled in a valid ballot. Then she separates the ballot along the perforations and submits all three parts to the election officials. At this moment, the voter is allowed to randomly choose one of three parts, make a photocopy of it, and take the photocopy home as her receipt.

Later, all the received ballot parts will be published on the WBB. The voter can then use her receipt to check whether it is correctly displayed. Otherwise, the receipt can be used as the proof to make a complaint. Note that if any part of the voter's ballot has been altered or removed from the WBB, she will have at least 33 percent probability to detect the cheating. Finally, the election result is calculated using the recorded ballot parts on the WBB, and this process can be publicly verified. Suppose there are n voters, and the candidates A, B and C have received a, b, and c marked bubbles, respectively. Then the actual votes received by each voter are calculated by subtracting n from a, b, c, respectively.

Because no complicated crypto technique is used in these non-crypto voting schemes, they are easy to understand and can be used to explain the basic ideas of verifiable voting schemes to ordinary people without special knowledge. However, they normally require much stricter assumptions than their crypto counterparts. For example, in Randell and Ryan's scheme, for any received ballot, it is important that its scratch strip not be removed by dishonest election officials before the tally. Otherwise, this ballot will be treated as invalid, and it will not be included in the tally. In the ThreeBallot scheme, election integrity relies on the fact that the machine to check the ballot validity is honest. Moreover, the election officials should not know which part of the ballot has been photocopied as the receipt. Otherwise, they can replace the other parts without being detected. Therefore, the non-crypto schemes are normally viewed as academic proposals rather than practical proposals.

Remote Voting schemes

All verifiable voting schemes introduced above require voters to cast their votes in the voting booth. However, this is not convenient for voters who are not able to attend the voting booth on the election day. To solve this issue, several verifiable remote voting schemes have been introduced. However, because voters are not protected from adversaries when they cast their votes, many of these schemes do not ensure the same security level as the supervised voting schemes. Here, we describe a novel remote voting scheme that not only achieves end-to-end verifiability, but also provides very high-level coercion protection to the voters.[10] Because this scheme was introduced by Juels, Catalano, and Jakobsson in [5], it is normally referred to as the JCJ scheme. This scheme works as follows:

1. *Registration phase:* Before the election, every voter needs to register herself in some controlled environment. Once authenticated, the voter V_i will be provided with a credential σ_i, which is generated by some trusted party. After that, the election authorities encrypt this credential using the ElGamal encryption as $E_{pk}(\sigma_i)$, where pk is a public key and its corresponding secret key is threshold shared among a number of tellers. This ciphertext will be published onto the WBB in a list L. Then the authorities prove to V_i that this process is executed properly using the DVP protocol. Note that the voter needs to remember her credential σ_i, and it could be used in many different elections.
2. *Voting phase:* Suppose V_i wants to vote for the candidate m_i; she calculates two encrypted values as

$$c_i^{(1)} = E_{pk}(m_i),\ c_i^{(2)} = E_{pk}(\sigma_i)$$

Then V_i submits her vote $v_i = (c_i^{(1)}, c_i^{(2)}, \delta_i)$ to the WBB through an anonymous channel, where δ_i is a zero-knowledge proof that V_i knows the plaintexts of both ciphertexts.

10. Apart from the privacy and receipt-freeness properties offered by many supervised voting schemes, it also provides protection against three other attacks: the randomization attack, the forced abstention attack, and the simulation attack.

3. *Tallying phase:* After the Election Day, election authorities collect all received votes on the WBB. They first check the proof δ_i of each vote, and any vote with an invalid proof will be eliminated immediately. Then for the remaining votes that form a list L_1, the authorities perform the Plaintext Equivalent Test (PET) between every two votes in L_1. This process ensures that if several received votes use the same credential (either valid or invalid), only the last submitted one will be retained and the others are removed from the list L_1. At this moment, the remaining votes form a list L_2. Then the authorities shuffle the list L_2 using mixnets, resulting in a list $L_{2'}$. As follows, these authorities perform pairwise PET checks between $L_{2'}$ and L. If any vote in $L_{2'}$ cannot be matched with an encrypted credential in L, it means that this vote contains an invalid credential and it will be removed from $L_{2'}$. Finally, the remaining votes form a list L_3, and it will be threshold decrypted by a quorum of tellers to reveal the election result.

To see the ways in which JCJ scheme achieves verifiability, the voter can verify that her encrypted credential $E_{pk}(\sigma_i)$ has been included in the list L and her encrypted vote v_i has reached the WBB. Also, it can be verified by the public that the tallying phase is correctly performed. If adversaries coerce the voter to reveal her credential, she can simply reveal a fake one. This is because adversaries cannot distinguish a fake credential from a real one. Moreover, if adversaries use this fake credential to cast a vote, it will be removed in the tallying phase, but they are unable to find out whether or not their cast vote has been removed.

Prêt à Voter

Prêt à Voter [52] was inspired by Chaum's voting scheme [47], replacing the conceptually and technologically rather complex visual cryptography with a simpler device of permuting the candidate order on each ballot. Each voter is given a ballot form with an independent permutation of candidates printed down the left-hand side and an encryption of the permutation is printed on the right-hand side.

The voting ceremony is as follows. The voter picks a random ballot form at the polling station. The ballot forms will be sealed in envelopes for privacy. A typical ballot form is shown in Figure 69.7. In the privacy of a booth, the voter marks the chosen candidate on the right-hand side of the form. She then separates the two sides and destroys the LHS. Exiting the booth, she takes the RHS to be scanned and recorded by the system. The RHS is validated as cast, for example, by digital signing and franking by the officials. This is retained as a receipt that

she can later check against a WBB to verify that her vote has been correctly registered.

Note that due to the permutation of candidates, the vote cannot be inferred from the RHS alone without decrypting the onion, thereby ensuring ballot privacy. Receipt-freeness relies on destruction of the LHS, hence eliminating the link between the LHS and RHS of the ballot.

After voting has ended, the receipts posted to the WBB pass through a series of anonymizing mixes. Decrypted votes are then published on the WBB for public verification. Ballot generation and tabulation are discussed in the following.

The way in which the vote is encoded in the receipt has a number of important consequences that distinguish it from previous schemes. First, the voter is not required to communicate her choice to an encryption device. This sidesteps threats arising from the possibility of a corrupt device leaking information about votes via side-channels or subliminal channels. Second, ballot auditing is very clean: Correct encoding of the vote follows from correct construction of the ballot form. Thus, ballot auditing is performed on the ballot forms rather than on the receipts, as would be the case for other verifiable schemes. Whether or not a ballot form is correctly constructed is a simple binary decision and is independent of the vote or indeed the voter. Contrast this with earlier schemes: The voter inputs a choice, and the device produces one or more encryptions of this. Suppose that the voter chooses to audit this: The encryption is opened ,and the plaintext is compared with the claimed input. In the event that the voter claims that the decryption does not match her input, the difficulty lies in how to distinguish the two situations: The device is corrupt and has encrypted the wrong vote; or the voter is mistaken or is lying about her input. A further difficulty is that auditing can undermine ballot privacy. Of course, a voter who intends to audit can input a dummy vote, but this requires a certain level of understanding that not all voters may possess.

Another way of phrasing this is that in Prêt à Voter, what is encrypted is not the vote itself but rather the (randomized) frame of reference in which the vote is encoded. This step can be performed before the ballot form is associated with a vote or voter.

Evolution of Prêt à Voter

Since its inception, Prêt à Voter has undergone a number of changes, and several design options have been identified. We focus here on some of the more important changes and options, highlighting some of the associated issues and challenges. In many cases the driving force behind changes to the system has been to address particular scenarios or contexts and the additional perceived threats that may become relevant in those circumstances. Sometimes enhancements are for practical reasons—for example, to improve the efficiency of the scheme or the availability of new cryptographic primitives.

Tabulation Issues

The original versions of Prêt à Voter used RSA decryption mixes. This has the advantage of allowing the receipts to be transformed as they go through the mixes so that they emerge in the canonical frame of reference. More precisely, the final candidate permutation on the ballot is formed as the product of several permutations, each defined in a layer of the onion. As a receipt moves through the mix, the server reveals the seed value encrypted at the layer in question, computes the inverse permutation, and transforms the index or vector accordingly. The index/rank vector emerges in the canonical frame or reference, that is, in the canonical candidate order. This conveniently removes all information about the permuted candidate order during the mixing.

The downside of decryption mixes is that they lack robustness and flexibility. Mixing and tabulation are intertwined: Each server must hold a decryption key, and the order in which votes are decrypted must be predetermined. Another problem is that the onions grow in size with the number of mixes and the size of the seed space for each layer. These considerations led to the introduction of re-encryption mixes and using ElGamal in place of RSA [53].

With re-encryption mixes, the mixing and decryption phases can be separated. Mix servers do not require secret keys and their ordering does not need to be predetermined, so they can be easily replaced if any one fails. Full mixing of terms in the group is possible, and the onion size is independent of the number of mixes. Perhaps most importantly, many re-encryption mixes can be run in parallel or sequence. Further, if a mix is found to be flawed, it can be rerun and reaudited fairly easily. As decryption mixes are deterministic, they cannot be audited or rerun without compromising privacy.

Permutations of the Candidate Order

A re-encryption mix does not involve (partial) decryption at each stage, so there is no obvious way to mimic the construction above (to transform the index/vector while preserving the meaning). One possibility is to leave the index/vectors invariant. An attacker could partition the mix according to the index values with possible privacy issues, but this is not necessarily a problem if the number of voters greatly outnumbers the number of voting options. In [53], this issue is dealt with by restricting to cyclic shifts of the candidates and exploiting the homomorphic property of ElGamal to absorb the index into the onion, thereby allowing conventional re-encryption mixes to be used. From a secrecy point of view, this is enough to conceal the choice of a single candidate. It is not enough to conceal the choice in more elaborate voting methods such as STV. It is also arguably rather fragile from an integrity point of view: If an adversary has a way to alter ballots in an undetectable way and he wants to shift votes from one candidate to another, he applies the appropriate shift to the index value.

A number of attempts have been made to go beyond cyclic shifts while employing re-encryption mixes in Prêt à Voter. Ryan and Teague [54] propose use of affine permutations of the candidate order while retaining receipt-freeness. The set of possible permutations is defined by a shift and a scaling. This largely eliminates the shift attack described above, while only using one pair of onions.

An obvious approach to handling full permutations is to introduce n onions per ballot (where n is the number of candidates) [55,56]. However, this becomes computationally intensive as the number of candidates grows. Handling full permutations in a re-encryption mix in a more elegant way is an ongoing research problem.

Leakage of Ballot Information

In the case of Prêt à Voter, although no device actually learns the voter's choice, there is still the possibility of a subliminal channel attack: The entity creating the ballot forms secretly encodes information about the permutation in the ciphertext by, for example, selecting the randomization of the encryption in such a way that a secret keyed hash applied to the onion leaks information about the candidate order. These are known as kleptographic attacks [57,58].

A possible counter to such an attack is the use of pseudorandom rather than pure random values. Where ballots are created on demand by a device in the booth, the randomization factor of the encryption could, for example, be derived from a signature applied to a serial number printed on the ballot, or using Verifiable Random Functions [59]. Alternatively, we can use a distributed construction of the ballots in such a way that no single entity knows sensitive information: the final candidate order, the randomization factors, and so on [60,61].

Coercion

"Classic" Prêt à Voter is vulnerable to certain types of coercion such as randomization and "Italian" attacks, particularly with ranked voting methods.

In the randomization attack, the coercer demands that the voter produce a receipt with a mark at a prespecified position, regardless of which candidate this represents. This is tricky to counter in any simple way, but if Benaloh challenges are available, the voter can obtain further receipts until she finds one that allows her to vote as she intends while satisfying the coercer's demands. This works quite well for simple elections with a small number of options on the ballot, but is not feasible for more complex voting methods such as STV.

Chain-voting

This attack, which is also effective against conventional voting systems, is particularly virulent in verifiable schemes. An adversary obtains an unused ballot form, marks it with his chosen candidate, and passes it to a voter, who is required to obtain a fresh ballot at the polling station but to submit the premarked form. The coerced voter smuggles out her unused ballot form, hands it over to the adversary, and so the chain continues.

A possible countermeasure is to use serial numbers on the ballot forms, for officials to note the serial number when the ballot form is issued, and to check it before the vote is cast, similar to the mechanism suggested by Jones [62].

6. THREATS TO VERIFIABLE VOTING SYSTEMS

The failure of voters to verify their receipts against the WBB can impact on the integrity of a system. A possible countermeasure is a Verifiable Encrypted Paper Audit Trail (VEPAT) mechanism [63] in which hard copies of receipts are stored securely and used to perform independent checks against the receipts posted to the WBB. Theoretically, a VEPAT may be useful in the event of a dispute, but in practice, tracing individual receipts in a large election could prove difficult.

In the "Italian" attack, an adversary may demand that the voter fill in the ballot in a very specific way that serves, with high probability as a unique identifier for that ballot. This is potentially very effective where there is a large number of options on the ballot (STV with a significant number of candidates). Such attacks are particularly problematic in verifiable schemes in which decrypted ballots are publicly posted. Countermeasures such as lazy decryption [64] can mitigate this problem by avoiding revealing full ballots at any stage of the tabulation process, but they are computationally intensive and do not eliminate all leakage.

Authentication of Receipts

With receipted schemes, anti-faking mechanisms are important both to prevent dishonest voters from discrediting an election and to help avoid a dishonest system cheating voters. Digital signatures or franking applied to receipts are possibilities but, especially with the former, can be difficult for voters to verify without easily accessible technology.

Ryan has discussed human-verifiable methods such as special printing or paper [65]. In practice, both digital signatures and anticounterfeiting may be necessary: Digital signatures to verify ballot construction and anticounterfeiting to protect the system against fraudulent ballot receipts. Possible mechanisms, practical implementation, and associated issues are important research questions.

Use of Cryptography

Modern cryptography appears to be perfectly suited to solving the apparent conflict between verifiability and privacy in voting systems, but there are obstacles to its deployment.

Establishing understanding and trust in the mechanisms and guarantees provided by cryptographic systems is not straightforward. In addition, proper implementation of cryptography can be complicated and problematic. Because the privacy afforded by cryptographic means is usually computational, there may be concerns about the long-term privacy of votes. Schemes have been devised, however, to provide everlasting privacy [66,67].

An encryption-free, paper-based voting system, conceptually similar to [50], has been described earlier under Randell and Ryan's scheme. The relative simplicity of the system, together with its similarity to lottery card games, may be helpful in gaining voter confidence and trust.

7. SUMMARY

Conducting elections in a way that ensures a demonstrably correct outcome, while at the same time ensuring that all ballots remain secret, has been a challenge to the very foundations of democracy from the outset. The history of democracy is a constant battle between those who seek to guarantee the integrity of elections and those who seek to undermine and corrupt the outcome. Many technologies have been applied to address this challenge, especially in the United States, but none has been wholly successful. More recently, as described in this chapter, cryptographers and security experts have turned their attention to the problem. In many ways, this presents a unique and especially demanding challenge: There is no "god's eye" view to tell us what the correct outcome of an election should be, and consequently a voting system can fail in a

nonmanifest fashion. This is in contrast to most other critical systems, for example, Internet banking and avionics, to which voting is sometimes compared. Such comparisons are misleading however, precisely because in these applications failures are manifest and, in the case of banking at least, usually correctable.

A number of cryptographically based schemes have emerged in the last few years which hold out the promise of fully verifiable elections: where the outcome can be proved correct with minimal trust assumptions. In this chapter, we have outlined some of the most notable and promising of these schemes, along with the cryptographic primitives required in their construction. Several of these schemes have been implemented and even subjected to trial. For example, the Scantegrity II scheme has been used in municipal elections in Takoma Park in the United States, and Prêt à Voter is currently being adapted for use in the State of Victoria in Australia.

Despite the significant advances in verifiable voting, we have yet to see significant deployment of such schemes. An interesting question then is: Why has there been so little uptake to date? It appears that the main obstacle is the use of cryptography, which many stakeholders regard with suspicion. Thus, the major challenge now is to present these schemes in a way that will convince the stakeholders of the security properties they afford. It is true that the concepts underlying "modern cryptography" are subtle and the arguments showing that verifiable schemes indeed achieve the claimed security properties are quite sophisticated, so it is unreasonable to expect the average voter to follow all the details. But then, people routinely use cryptography for Internet shopping and the like without understanding all the intricacies. It is to be hoped therefore that, properly presented and after a period of informed debate, verifiable schemes will find their place in supporting democracy. It would seem sensible to initially deploy such schemes for less critical elections: officials of student bodies, professional societies, and so on, before use in real, binding political elections.

Verifiable voting systems remain an active area of research, and doubtless there are further breakthroughs to be made. Various challenges and open questions remain, aside from the previously mentioned challenge of overcoming the natural aversion to cryptography. A prime example is how to perform systematic analysis of a voting system as a sociotechnical system—that is, a system comprising not only technical components such as the cryptographic algorithms and protocols, but also humans and procedures.

In this chapter we have focused on polling station/ supervised elections. There is considerable interest in remote voting, in particular Internet voting. Here the challenges are even more daunting than for supervised voting, and, in particular, there is no way to ensure that a coercer does not interact with the voter. Some elegant theoretical approaches to countering coercion in the remote context have been proposed, but it seems fair to say that none are sufficiently simple and understandable to be effective in practice.

Finally, let's move on to the real interactive part of this chapter: review questions/ exercises, hands-on projects, case projects, and optional team case project. The answers and/ or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? There are many general challenges involved in running a voting system securely, which are common to any complex secure system, and any implementation will need to take account of these.
2. True or False? While e-voting systems often vary widely in design and operation, they generally converge on a standard set of security requirements.
3. True or False? Coercion-resistance is a weaker form of receipt-freeness, which can be described as the inability of a voter to prove how he or she voted.
4. True or False? The privacy, receipt-freeness, and integrity properties need to be considered in only the front-end.
5. True or False? An e-voting system may only satisfy a subset of the desirable security properties.

Multiple Choice

1. The __________ has three components: cast-as-intended, recorded-as-cast, and counted-as-recorded.
   A. reputation
   B. Internet filters
   C. ground-based threat
   D. verifiability property
   E. content-control software
2. To achieve the __________, the individual voter needs to verify that the encrypted vote contains his or her intended vote.
   A. cast-as-intended property
   B. Web content filtering
   C. scale
   D. baseband signals
   E. active monitoring
3. The design philosophy for __________ is similar in both verifiable supervised and remote voting schemes.
   A. the Basic Interoperable Scrambling System (BISS)
   B. Rapleaf
   C. Worms

D. verifiability
E. security

4. In____________, anyone can encrypt a message using the public key, and the encrypted message can only be decrypted by the party who possesses the corresponding ^ secret key
A. PowerVu
B. denial-of-service attack
C. public-key encryption
D. port traffic
E. taps

5. __________ work(s) as follows: Let p, q be two large primes such that q|p − 1.
A. The ElGamal cipher
B. The DigiCipher 2 (DCII)
C. The denying service
D. Decision making
E. URL lists

EXERCISE

Problem

In secret sharing and threshold techniques, the secret information (the secret key) is shared among several parties, and a quorum of these parties can work together to recover the information. Please expand on this.

Hands-On Projects

Project

A zero-knowledge proof allows the prover to prove some fact to the verifier without revealing the secret details of the fact. Please explain further in explicit detail.

Case Projects

Problem

The witness hiding/indistinguishable protocol was introduced by Cramer, Damgård, and Schoenmakers; therefore, it is also known as the CDS protocol. Please explain further in explicit detail.

Optional Team Case Project

Problem

A mixnet is a cryptographic building block implemented by a number of mix servers. Please explain further in explicit detail.

Chapter 70

Advanced Data Encryption

Pramod Pandya
CSU Fullerton

1. MATHEMATICAL CONCEPTS REVIEWED

In this section we introduce the necessary mathematics of cryptography: Integer and Modular Arithmetic, Fermat's Theorem [1]:

Euler's Phi-Function $\phi(n)$

Euler's totient function finds the number of integers that are both smaller than n and coprime to n:

1. $\phi(1) = 0$
2. $\phi(p) = p-1$ if p is a prime
3. $\phi(m \times n) = \phi(n) \times \phi(m)$ if m, and n are coprime
4. $\phi(p^e) = p^e - p^{e-1}$ if p is a prime

Examples:

$\phi(2) = 1; \phi(3) = 2; \phi(4) = 2; \phi(5) = 4; \phi(6) = 2; \phi(7) = 6;$
$\phi(8) = 4$

Fermat's Little Theorem

In the 1970s, the creators of digital signatures and public-key cryptography realized that the framework for their research was already laid out in the body of work by Fermat and Euler. Generation of a key in public-key cryptography, involves an exponentiation modulo in a given modulus:

$a \equiv b \pmod m$ then $a^e \equiv b^e \pmod m$ for any positive integer e
$a^{e+d} \equiv a^e \,.\, a^d \pmod m$
$(ab)^e \equiv a^e \,.\, b^e \pmod m$
$(a^d)^e \equiv a^{de} \pmod m$

Theorem: Let p be a prime number:

1. If a is coprime to p, then $a^{p-1} \equiv 1 \pmod p$
2. $a^p \equiv a \pmod p$ for any integer a

Theorem: Let p and q be distinct primes:

1. If a is coprime to pq, then

$$a^{k(p-1)(q-1)} \equiv 1 \pmod{pq}, \text{k is any integer}$$

2. For any integer a,

$$a^{k(p-1)(q-1)+1} \equiv a \pmod{pq},\ \text{k is any positive integer}$$

Discrete Logarithm

In this section we will deal with multiplicative group $G = <Z_{n*}, x>$. The order of a finite group is the number of elements in the group G. Let us take an example of a group,

$$G = <Z_{21*},\ x>$$

$\phi(21) = \phi(3) \times \phi(7) = 2 \times 6 = 12$, that is, 12 elements in the group, and each is coprime to 21.

$$\{1, 2, 4, 5, 8, 10, 11, 13, 16, 17, 19, 20\}$$

The order of an element, ord(a), is the smallest integer i such that

$$a^i \equiv e \pmod n, \text{where } e = 1.$$

Find the order of all elements in $G = <Z_{10*}, x>$

$\phi(10) = \phi(2) \times \phi(5) = 1 \times 4 = 4$

$\{1, 3, 7, 9\}$

Primitive Roots

In the multiplicative group $G = <Z_{n*}, x>$, when the order of an element is the same as $\phi(n)$, then that element is called the primitive root of the group.

$G = <Z_{8*}, x>$ has no primitive roots. The order of this group is, $\phi(8) = 4$

$$Z_{8*} = \{1, 3, 5, 7\}$$

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00070-2

1, 2, 4 each divide the order of the group which is 4:

$$1^1 \equiv 1 \pmod 8 \qquad \rightarrow \text{ord}(1) = 1$$
$$3^1 \equiv 3 \pmod 8;\ 3^2 \equiv 1 \pmod 8 \qquad \rightarrow \text{ord}(3) = 2$$
$$5^1 \equiv 5 \pmod 8;\ 5^2 \equiv 1 \pmod 8 \qquad \rightarrow \text{ord}(5) = 2$$
$$7^1 \equiv 7 \pmod 8;\ 7^2 \equiv 1 \pmod 8 \qquad \rightarrow \text{ord}(7) = 2$$

In the example above, none of the elements have an order of 4; hence this group has no primitive roots. The group $G = < Z_{n*}, x >$ has primitive roots only if n is 2, 4, p^t, or $2p^t$, where p is an odd prime not including 2 and t is an integer.

If the group $G = < Z_{n*}, x >$ has any primitive roots, the number of primitive roots is $\phi(\phi(n))$. If a group, $G = < Z_{n*}, x >$ has primitive roots, then it is cyclic, and each of its primitive root is a generator of the whole group.

Group $G = < Z_{10*}, x >$ has two primitive roots because $\phi(10) = 4$, and $\phi(\phi(10)) = 2$. These two primitive roots are {3, 7}:

$$3^1 \bmod 10 = 3\ 3^2 \bmod 10 = 9\ 3^3 \bmod 10 = 7\ 3^4 \bmod 10 = 1$$

$$7^1 \bmod 10 = 7\ 7^2 \bmod 10 = 9\ 7^3 \bmod 10 = 3\ 7^4 \bmod 10 = 1$$

Group, $G = <Z_{p*}, x>$ is always cyclic.

The group $G = <Z_{p*}, x>$ has the following properties:

1. Its elements are from 1 to (p − 1) inclusive.
2. It always has primitive roots.
3. It is cyclic, and its elements can be generated using g where x is an integer from 1 to $\phi(n) = p - 1$.
4. The primitive roots can be used as the base of logarithm—discrete logarithm.

Modern encryption algorithms such as DES, AES, RSA, and ElGammal to name a few are based on algebraic structures such as Group Theory and Field Theory as well as Number Theory. We will begin with a set S, with finite number of elements, and a binary operation (*) defined between any two elements of the set:

$$*: S \times S \rightarrow S$$

that is, if a and $b \in S$, then $a*b \in S$. This is important, for it implies that the set is closed under the binary operation. We have seen that the message space is finite, and we want to make sure that any algebraic operation on the message space satisfies the closure property. Hence, we want to treat the message space as a finite set of elements. We will remind the reader that messages that get encrypted must be finally decrypted by the received party; thus encryption algorithm must run in polynomial time. Furthermore, the algorithm must have the property that it be reversible to recover the original message. The goal of encryption is to confuse and diffuse the hacker such that it would make it almost impossible for the hacker to break the encrypted message. Therefore, encryption must consist of finite number substitutions and transpositions. The algebraic structure, Classical Group, facilitates the coding of the encryption algorithm. Next we give some relevant definitions and examples before we proceed to introduce the essential concept of a Galois Field, which is central to formulation of the Rijndael algorithm used in the Advanced Encryption Standard (AES).

Definition Group

A group $(G, \bullet)$ is a finite set G together with an operation $\bullet$ satisfying the following conditions:

1. **Closure:** $\forall$ a, $b \in G$, then $(a \bullet b) \in G$
2. **Associatively:** $\forall$ a, b, $c \in G$, then $a \bullet (b \bullet c) = (a \bullet b) \bullet c$
3. **Existence of Identity:** $\exists$ a unique element $e \in G$ such that $\forall$ $a \in G$: $a \bullet e = e \bullet a$
4. $\forall a \in G$: $\exists\ a^{-1} \in G$: $a^{-1}a = a^{-1} \bullet a = e$

Definition of Finite and Infinite Groups (Order of a Group)

A group G is said to be finite if the number of elements in the set G is finite. Otherwise, the group is infinite.

Definition of Abelian Group

A group G is abelian if for all a, $b \in G$, $a \bullet b = b \bullet a$

The reader should note that in a group, the elements in the set do not have to be a number or objects: They can be mappings, functions, or rules.

Examples of a Group

The set of integers Z is a group under addition (+); that is, (Z, +) is a group with identity e = 0, and the inverse of an element a is (−a). This is an additive abelian group, but infinite.

Nonzero elements of Q (rationals), R (reals), and C (complex) form a group under multiplication, with the identity element e = 1, and a^{-1} being the multiplicative inverse. For any $n \geq 1$, the set of integers modulo n forms a finite additive group of n elements:

$G = < Z_n, + >$ is an abelian group.

The set of Z_{n*} with multiplication operator, $G = < Z_{n*}, x >$ is also an abelian group. The set Z_{n*}, is a subset of Z_n and includes only integers in Z_n that have a unique multiplicative inverse:

$$Z_{13} = \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12\}$$

$$Z_{13*} = \{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12\}$$

Definition Subgroup

A subgroup of a group G is a nonempty subset H of G, which itself is a group under the same operations as that of G. We denote that H is a subgroup of G as $H \subseteq G$, and $H \subset G$ is a proper subgroup of G if the set $H \neq G$. Examples of Subgroups:

Under addition, $Z \subseteq Q \subseteq R \subseteq C$.

$H = < Z_{10}, + >$ is a proper subgroup of $G = < Z_{12}, + >$

Definition of Cyclic Group

A group G is said to be cyclic if there exists an element $a \in G$ such that for any $b \in G$, and $i \geq 0$, $b = a^i$. Element a is called a generator of G. The group $G = < Z_{10^*}, x >$ is a cyclic group with generators g = 3 and g = 7:

$$Z_{10*} = \{1, 3, 7, 9\}$$

The group $G = < Z_6, + >$ is a cyclic group with generators g = 1 and g = 5:

$$Z_6 = \{0, 1, 2, 3, 4, 5\}$$

Rings

Let R be a nonempty set with two binary operations: addition (+) and multiplication (*).

Then R is called a ring if the following axioms are met:

1. Under addition, R is an abelian group with zero as the additive identity.
2. Under multiplication, R satisfies the closure, associative, and identity axiom. 1 is the multiplicative identity, and that $1 \neq 0$.
3. For every a, and b that belongs to R, $a \bullet b = b \bullet a$.
4. For every a, b, and c that belongs to R, then $a \bullet (b + c) = a \bullet b + a \bullet c$

Examples

Z, Q, R, and C are all rings under addition and multiplication. For any $n > 0$, Z_n is a ring under addition and multiplication modulo n with 0 as identity under addition, 1 under multiplication.

Definition Field

If the nonzero elements of a ring form a group under multiplication, then the ring is called a field.

Examples

Q, R, and C are all fields under addition and multiplication, with 0 and 1 as identity under addition and multiplication.

[Note that Z under integer addition and multiplication is not a field because any nonzero element does not have a multiplicative inverse in Z.]

Finite Fields GF(2^n)

Construction of finite fields and computations in finite fields are based on polynomial computations. Finite fields play a significant role in cryptography and cryptographic protocols such as the Diffie and Hellman key exchange protocol, ElGamal cryptosystems, and Advanced Encryption Standard (AES):

For a prime number p, the quotient Z/p (or F_p) is a finite field with p number of elements. For any positive integer q, $GF(q) = F_q$

We define A to be algebraic structure such as a ring or a group or a field.

Definition

A polynomial over A is an expression of the form:

$$f(x) = \sum_{i=0}^{n} a_i x^n$$

where, n is a nonnegative integer, the coefficient $a_i \in A$, $0 \leq i \leq n$, and $x \notin A$.

Definition

A polynomial $f \in A[x]$ is said to be irreducible in A[x] if f has a positive degree and $f = gh$ for some g, $h \in A[x]$ implies that either g or h is a constant polynomial. The reader should be aware that a given polynomial can be reducible over one structure, but irreducible over another.

Definition

Let f, g, q, and $r \in A[x]$ with $g \neq 0$. Then we say that r is remainder of f divided by g:

$$r \equiv f(\text{mod } g)$$

The set of remainders of all the polynomials in A[x] (mod g) denoted as $A[x]_g$.

Theorem

Let F be a field and f be a non-zero polynomial in F[x]. Then $F[x]_f$ is a ring, and is a field iff f is irreducible over F.

Theorem

Let F be field of p elements and f be irreducible polynomial over F. Then the number of elements in the field $F[x]_f$ is p^n.

For every prime p and every positive integer n there exist a finite field of p^n number of elements. For any prime number p, Z_p is a finite field under addition and multiplication modulo p, with 0 and 1 as the identity under addition and multiplication.

Z_p is an additive ring and nonzero elements of Z_p, denoted by Z_{p^*} form a multiplicative group. Galois Field, GF(p^n) is a finite field with number of elements p^n, where p is a prime number and n is a positive integer.

Example

Integer representation of Finite Field (Rijnadel) element. Polynomial $f(x) = x^8 + x^4 + x^3 + x + 1$ is irreducible over F_2.

The set of all polynomials (mod f) over F_2 forms a field of 2^8 elements; they are all polynomials over F_2 of degree less than 8. So any element in the field $F_2[x]_f$

$$b_7x^7 + b_6x^6 + b_5x^5 + b_4x^4 + b_3x^3 + b_2x^2 + b_1x^1 + b_0$$

where, $b_7, b_6, b_5, b_4, b_3, b_2, b_1, b_0 \in F_2$ Thus any element in this field can represent a 8-bit binary number.

Data inside a computer is organized in bytes (8 bits) and is processed using Boolean logic; that is, bits are manipulated using binary operation addition and multiplication. These binary operations are implemented using the logical operator XOR, or in the language of finite fields, GF(2). Since the extended ASCII defines 8-bit per byte, an 8-bit byte has a natural representation using a polynomial of degree 8. Polynomial addition would be mod 2, and multiplication would be mod polynomial degree 8. Of course this polynomial degree 8 would have to be irreducible. Hence the Galois Field GF(2^8) would be the most natural tool to implement the encryption algorithm. Furthermore, this would provide a close algebraic formulation. Consider polynomials over GF(2) with $p = 2$ and $n = 1$:

$$1,\ x,\ x + 1,\ x^2 + x + 1,\ x^2 + 1,\ x^3 + 1$$

Polynomials with negative coefficients, -1 is the same as $+1$ in GF(2). Obviously, the number of such polynomials is infinite. In algebraic operations of addition and multiplication, the coefficients are added and multiplied according to the rules that apply to GF(2). The set of such polynomials forms a ring.

Modular Polynomial Arithmetic over GF(2)

The Galois Field GF(2^3): Construct this field with eight elements that can be represented by polynomials of the form:

$$ax^2 + bx + c \text{ where } a, b, c \in GF(2) = \{0,\ 1\}$$

Two choices for a, b, c gives $2 \times 2 \times 2 = 8$ polynomials of the form:

$$ax^2 + bx + c \in GF_2[x]$$

What is our choice of the irreducible polynomials for this field?

$$(x^3 + x^2 + x + 1),\ (x^3 + x^2 + 1),\ (x^3 + x^2 + x),$$
$$(x^3 + x + 1),\ (x^3 + x^2)$$

These two polynomials have no factors: $(x^3 + x^2 + 1)$, $(x^3 + x + 1)$. So we choose polynomial $(x^3 + x + 1)$. Hence all polynomial arithmetic multiplication and division is carried out with respect to $(x^3 + x + 1)$. The eight polynomials that belong to GF(2^3):

$$\{0,\ 1,\ x,\ x^2,\ 1 + x,\ 1 + x^2,\ x + x^2,\ 1 + x + x^2\}$$

You will observe that GF(8) = {0,1,2,3,4,5,6,7} is not a field, since every element (excluding zero) does not have a multiplicative inverse such as {2, 4, 6) (mod 8).

Using a Generator to Represent the Elements of GF(2^n)

It is particularly convenient to represent the elements of a Galois Field with the help of a generator element. If α is a generator element, then every element of GF(2^n), except for the 0 element, can be written down as some power of α. A generator is obtained from the irreducible polynomial that was used to construct a finite field. If $f(\alpha)$ is the irreducible polynomial used, then α is that element that satisfies the equation $f(\alpha) = 0$. You do not actually solve this equation for its roots since an irreducible polynomial cannot have actual roots in the field GF(2). Consider the case of GF(2^3) defined with the irreducible polynomial $x^3 + x + 1$. The generator α is that element which satisfies $\alpha^3 + \alpha + 1 = 0$:

Suppose α is a root in GF(2^3) of the polynomial $p(x) = 1 + x + x^3$

that is, $p(\alpha) = 0$, then $\alpha^3 = -\alpha - 1 \pmod 2 = \alpha + 1$
$\alpha^4 = \alpha(\alpha + 1) = \alpha^2 + \alpha$
$\alpha^5 = \alpha^4.\alpha = (\alpha^2 + \alpha)\alpha = \alpha^3 + \alpha^2 = (\alpha^2 + \alpha + 1)$
$\alpha^6 = \alpha^5.\alpha = \alpha.(\alpha^2 + \alpha + 1) = (\alpha^2 + 1)$
$\alpha^7 = (\alpha^2 + 1).\alpha = (2\alpha + 1) = 1$

All powers of α generate nonzero elements of GF_8.

We will now consider all polynomials defined over GF(2), modulo the irreducible polynomial $x^3 + x + 1$. When an algebraic operation (polynomial multiplication) results in a polynomial whose degree equals or exceeds that of the irreducible polynomial, we will take for our result the remainder modulo the irreducible polynomial. For example,

$$(x^2 + x + 1) * (x^2 + 1) \bmod (x^3 + x + 1)$$
$$= (x^4 + x^3 + x^2) + (x^2 + x + 1) \bmod (x^3 + x + 1)$$
$$= (x^4 + x^3 + x + 1) \bmod (x^3 + x + 1)$$
$$= -x^2 + x$$
$$= x^2 + x$$

Recall that $1 + 1 = 0$ in GF(2). With multiplications modulo $(x^3 + x + 1)$, we have only the following eight polynomials in the set of polynomials over GF(2):

$$\{0,\ 1,\ x,\ x+1,\ x^2,\ x^2+1,\ x^2+x,\ x^2+x+1\}$$

We will refer to this set as $GF(2^3)$ where the power of 2 is the degree of the modulus polynomial. The eight elements of Z_8 are to be integers modulo 8. Similarly, $GF(2^3)$ maps all of the polynomials over GF(2) to the eight polynomials shown above. But you will note that the crucial difference between $GF(2^3)$ and 2^3: $GF(2^3)$ is a field, whereas Z_8 is NOT.

$GF(2^3)$ is a Finite Field

We know that $GF(2^3)$ is an Abelian group because the operation of polynomial addition satisfies all of the requirements on a group operator and because polynomial addition is commutative. $GF(2^3)$ is also a commutative ring because polynomial multiplication is a distributive over polynomial addition. $GF(2^3)$ is a finite field because it is a finite set and because it contains a unique multiplicative inverse for every nonzero element.

$GF(2^n)$ is a finite field for every n. To find all the polynomials in $GF(2^n)$, we need an irreducible polynomial of degree n. In general, $GF(p^n)$ is a finite field for any prime p. The elements of $GF(p^n)$ are polynomials over GF(p) (which is the same as the set of residues Z_p). Next we show how the multiplicative inverse of a polynomial is calculated using the Extended Euclidean Algorithm:

Multiplicative inverse of $(x^2 + x + 1)$ in $F_2[x]/(x^4 + x + 1)$ is $(x^2 + x)$

$(x^2 + x)\ (x^2 + x + 1) = 1 \bmod (x^4 + x + 1)$

Multiplicative inverse of $(x^6 + x + 1)$ in $F_2[x]/(x^8 + x^4 + x^3 + x + 1)$ is $(x^6 + x^5 + x^2 + x + 1)$

$(x^6 + x + 1)\quad (x^6 + x^5 + x^2 + x + 1) = 1 \quad \bmod (x^8 + x^4 + x^3 + x + 1)$ [1][2]

2. THE RSA CRYPTOSYSTEM

Now that we have reviewed the necessary mathematical preliminaries, we will focus on the subject matter of Asymmetric Cryptography, which uses a public and a private key to encrypt and decrypt the plaintext. If Alice wants to send plaintext to Bob, then she will use Bob's public key, which is advertised by Bob, to encrypt the plaintext, and then send it to Bob via an insecured channel. Bob would decrypt the data using his private key, which is known to him only. Of course, this would appear to be an ideal replacement for Symmetric-key cipher, but it is much slower since it has to encrypt each byte; hence it is useful in message authentication and communicating the secret key. See the following Key Generation Algorithm:

1. Select two prime numbers p and q such that $p \neq q$.
2. Construct $m = p \times q$.
3. Set up a commutative ring $R = \langle Z_m, +, x \rangle$ which is public since m is made public.
4. Set up a multiplicative group $G = \langle Z^*_{\phi(m)}, x \rangle$ which is used to generate public and private keys. This group is hidden from the public since $\phi(m)$ is kept hidden.
5. $\phi(m) = (p - 1)(q - 1)$
6. Choose an integer e such that $1 < e < \phi(m)$ and e is coprime to $\phi(m)$.
7. Compute the secret exponent d such that, $1 < d < \phi(m)$ and that $ed \equiv 1 \pmod{\phi(m)}$.
8. The public key is "e" and the private key is "d".
9. The value of p, q, and $\phi(m)$ are kept private.

Encryption:

1. Alice obtains Bob's public key (m, e).
2. The plaintext x is treated as a number to lie in the range $1 < x < m - 1$.
3. The ciphertext corresponding to x is $y = x^e \pmod m$.
4. Send the ciphertext y to Bob.

Decryption:

1. Bob uses his private key (m, d).
2. Computes the $x = y^d \pmod m$.

Why RSA works

$$y^d \equiv (x^e \bmod m)^d$$
$$\equiv (x^{ed}) \bmod m$$
$$d \,.\, e = 1 + km = 1 + k(p-1)(q-1)$$
$$y^d \equiv x^{ed} \equiv x^{1+k(p-1)(q-1)} \equiv x(\bmod m)$$

Example:

Choose $p = 7$ and $q = 11$, then $m = p \times q = 7 \times 11 = 77$

$R = < Z_{77}, +, x >$ and $\phi(77) = \phi(7)\ \phi(11) = 6 \times 10 = 60$

The corresponding multiplicative group $G = < Z^*_{60}, x >$

Choose $e = 13$ and $d = 37$ from Z^*_{60} such that $e \times d \equiv 1 \pmod{60}$

Plaintext = 5 $\quad y = x^e \pmod m = 5^{13} \pmod{77} = 26$

$x = y^d \pmod m = 26^{37} \pmod{77} = 5$

Note: 384-bit primes or larger are deemed sufficient to use RSA securely. The prime number $e = 2^{16} + 1$ is often used in modern RSA implementations.

Factorization Attack

The RSA algorithm relies on the fact that p and q are the distinct prime numbers; and, must be kept secret, even though m = p x q is made public. So if n is an extremely large number, then the problem reduces to finding the factors that make up the number n, which is known as the factorization attack. If the middle man, Eve, can factor n correctly, then she guesses correctly p, q, and $\phi(m)$. Remind yourselves that if the public key e is public, then Eve has to compute the multiplicative inverse of e:

$$d \equiv e^{-1} \pmod m$$

So if the modulus m is chosen to be 1024 bits long, then it would take considerable time to break the RSA system unless an efficient factorization algorithm could be found [1][2].

Chosen-Ciphertext Attack

Z_n is a set of all positive integers from 0 to $(n-1)$.

Z^*_n is a set all integers such that $\gcd(n,a) = 1$, where $a \in Z^*_n$.

$$Z^*_n \subset Z_n$$

$\Phi(n)$ calculates the number of elements in Z^*_n that are smaller than n and coprime to n.

$$\Phi(21) = \Phi(3) \times \Phi(7) = 2 \times 6 = 12$$

Therefore the number of integers in $\in Z_{21}{}^*$ is 12.

$Z^*_{21} = \{1, 2, 4, 5, 8, 10, 11, 13, 16, 17, 19, 20\}$, each of which is coprime to 21

$Z^*_{14} = \{1, 3, 5, 9, 11, 13\}$, each of which is coprime to 14

$\Phi(14) = \Phi(2) \times \Phi(7) = 1 \times 6 = 6$ number of integers in Z^*_{14}

Example:

Choose $p = 3$ and $q = 7$, then $m = 3 \times 7 = 21$,

Encryption and decryption take place in the ring, $R = < Z_{21}, +, x >$.

$$\Phi(21) = \Phi(2)\ \Phi\ (6) = 12$$

Key-Generation Group, $G = < Z^*_{12},\ x >$

$$\Phi(12) = \Phi(4)\Phi(3) = 2 \times 2 = 4 \text{ number in } Z^*_{12}$$

$$Z^*_{12} = \{1, 5, 7, 11\}$$

Alice encrypts the message P using the public key e of Bob and sends the encrypted message C to Bob:

$$C = P^e \bmod m$$

Eve the middle man intercepts the message and manipulates the message before forwarding to Bob:

1. Eve chooses a random integer $X \in Z_m{}^*$ (since m is public).
2. Eve calculates $Y = C \text{ x } X^e \pmod m$.
3. Bob receives Y from Eve, and he decrypts Y using his private key d.
4. $Z = Y^d \pmod m$.
5. Eve can easily discover the plaintext P as follows:
   $Z = Y^d \pmod m = [C \text{ x } X^e]^d \pmod m = [C^d \text{ x } X^{ed}] \pmod m = [C^d \text{ x } X] \pmod m$

   Hence $Z = [P \text{ x } X] \pmod m$

Eve, using the Extended Euclidean Algorithm, can then compute the multiplicative inverse of X and thus obtain P:

$$P = Z \text{ x } X^{-1} \pmod m$$

The eth Roots Problem

Given:

1. a composite number n, the product of two prime numbers p and q
2. an integer $e \geq 3$
3. $\gcd(e, \Phi(n)) = 1$
4. an integer $c \in Z^*_{12}$
5. Find an integer m such that $m^e \equiv c \bmod n$[1,2].

Discrete Logarithm Problem

Discrete logarithms are perhaps simplest to understand in the group Z_{p*}, where p is the prime number. Let g be the generator of Z_{p*}; then the discrete logarithm problem

reduces to computing a, given (g, p, g^a mod p) for a randomly chosen $a < (p-1)$.

If we want to find the *kth* power of one of the numbers in this group, we can do so by finding its kth power as an integer and then finding the remainder after division by p. This process is called *discrete exponentiation*. For example, consider Z_{23*}

To compute 3^4 in this group, we first compute $3^4 = 81$, and then we divide 81 by 23, obtaining a remainder of 12. Thus $3^4 = 12$ in the group Z_{23*}

Discrete logarithm is just the inverse operation. For example, take the equation $3^k \equiv 12 \pmod{23}$ for k. As shown above $k = 4$ is a solution, but it is not the only solution. Since $3^{22} \equiv 1 \pmod{23}$, it also follows that if n is an integer then $3^{4+22n} \equiv 12 \times 1^n \equiv 12 \pmod{23}$. Hence the equation has infinitely many solutions of the form $4 + 22n$. Since 22 is the smallest positive integer m satisfying $3^m \equiv 1 \pmod{23}$, that is, 22 is the order of 3 in Z_{23*}, these are all solutions. Equivalently, the solution can be expressed as $k \equiv 4 \pmod{22}$ [1].

In designing public-key cryptosystems, two problems dominate the designs: the integer factorization problem and the discrete logarithm problem. Large instances of these problems are still intractable today.

Discrete logarithms have a natural extension into the realm of elliptic curves and hyperelliptic curves. And Elliptic ElGamal has proved to be a strong cryptosystem using elliptic curves and discrete logarithms. In the next part of the chapter, we will take a look at the discrete logarithm problem and discuss its application to cryptography.

Discrete Logarithm Problem (DLP)

The discrete logarithm problem in group G, given some generator α of a cyclic subgroup G^* of G and an element $\beta \in G^*$, is to find the element x, $0 \le x \le (p-2)$, such that $\alpha^x = \beta$. The most frequently used cryptosystem utilizing the DLP is ElGamal; we give an elliptic curve variant of ElGamal below [1–3]. For example:

ElGamal Cryptosystem:

Alice wants to talk secretly with Bob.

Setting up: Sometime in the past, Bob has created his keys in the following way:

1. Bob chooses a random large prime p and a generator α of the multiplicative group Z_p^*.
2. Bob chooses a random integer a where $1 \le a \le (p-2)$.
3. Bob computes α^a mod p.
4. The triple $e_B = (p, \alpha, \alpha^a)$ is the public key, and d_B (p, α, a) is the private key.

Alice obtains Bob's public key from some public key server.

Encryption: Alice wants to encrypt a plaintext M with the cipher $e_B = (e, d, n)$. She starts by choosing a random integer k where $1 \le k \le (p-2)$ and then encrypting the plaintext M into the cipher-text C:

$$E_{K_B}(M) = C = (\gamma, \delta) = (\alpha^k, M * (\alpha^a)^k \bmod p)$$

Alice then sends Bob the encrypted message C.

Decryption: Bob then decrypts the cipher-text $C = (\gamma, \delta)$ with the cipher

$d_B = (e, d, n)$ in the following manner:

$$D_{K_B}(C) = M = (\gamma^{-\alpha}) * \delta \bmod p$$

Lattice-based Cryptography—NTRU

An n-dimensional lattice (see Figure 70.1) is generated using n-linearly independent vectors:

$v_1, \ldots\ldots, v_n \ \varepsilon\ R^n$; these vectors are known as the basis of the lattice. There are infinite numbers of such bases that can generate the same lattice.

$$L(v_1, \ldots\ldots, v_n) = \left\{ \sum_{i=1}^{n} \alpha_i v_i | \alpha_i \ \varepsilon\ Z \right\}$$

In group theory, a lattice in R^n is a discrete subgroup of R^n which spans the real vector space R^n. A lattice is the symmetry group of discrete translational symmetry in n directions. Two NP-hard problems related to lattices are the shortest vector problem (SVP) and the closest vector problem (CVP; see Figure 70.2). Given an arbitrary basis for a lattice, find the SVP in the lattice or find the CVP to an arbitrary nonlattice vector. In both the quantum and classical computational problems, these problems are hard to solve for high-dimensional lattices (see Figure 70.3). There are a number of lattice-based cryptographic schemes, but the NTRU-based cryptographic algorithm appears to be most practical [4,5].

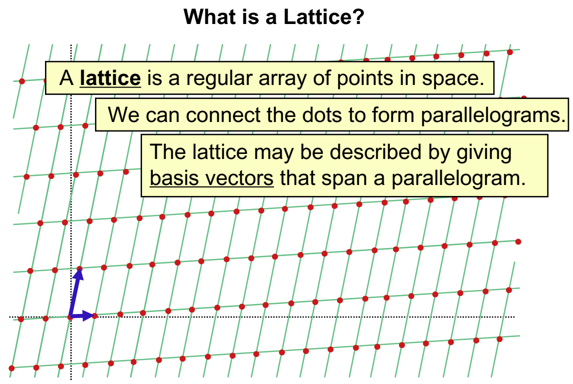

FIGURE 70.1 Definition of Lattice.

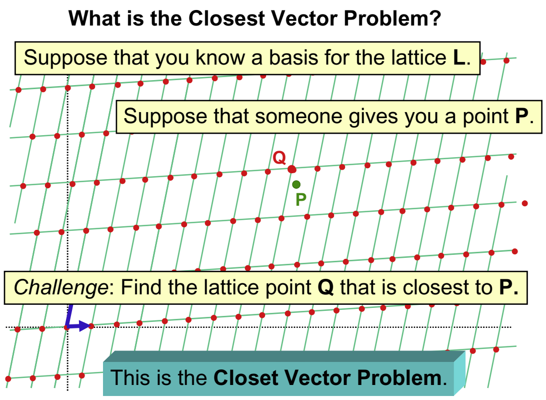

FIGURE 70.2 Closest vector problem (CVP).

Why Is That A Hard Problem?

For lattices in the plane, you're right, it's very easy.
It's not even very hard in dimension 3, or 4, or 5.
However, the Closest Vector Problem is **very hard** in high dimension, say in dimension 500.

FIGURE 70.3 The hard closest vector problem.

NTRU Cryptosystem

NTRU is not based on factorization or discrete logarithmic problems. Rather, it is a lattice-based alternative to RSA and ECC and is based on the shortest vector problem in a lattice. NTRU was founded in 1996 by three mathematicians: Jeffrey Hoffstein, Joseph H. Silverman, and Jill Pipher. Later on with the addition of yet another member, Daniel Lieman, to the team, NTRU Cryptosystems was incorporated in Boston. NTRU Cryptosystems was acquired by Security Innovation in 2009.

The NTRU cryptosystem was introduced at the rump session of Crypto'96 and was later published in the proceedings of the ANTS-III conference. NTRU is a ring-based public-key cryptosystem and is therefore quite different from the group-based cryptosystems whose security relies on the integer factorization problem or the discrete logarithm problem. This extra structure can be exploited to obtain a very fast cryptosystem: To encrypt/decrypt a message block of length N, NTRU only requires O(N^2) time, whereas the group-based schemes require O(N^3) time. Furthermore, NTRU also has a very short key size of O(N) and very low memory requirements, which makes it ideal for constrained devices such as smart cards.

Truncated Polynomial Rings

Consider a polynomial of degree (N − 1) having integer coefficients:

$$\mathrm{a} = a_0 + a_1X + a_2X^2 + a_3X^3 + a_4X^4 \ldots\ldots\ldots\ldots\ldots + a_{(N-1)}X^{(N-1)}$$

The set of all such polynomials is denoted by R. The arithmetic on the polynomials in R is as follows. Consider two polynomials a and b:

$$\mathrm{a} + \mathrm{b} = (a_0 + b_0) + (a_1 + b_1)X + \ldots\ldots + (a_{(N-1)} + b_{(N-1)})X^{(N-1)}$$

Suppose N = 3 and a = 2 − X + 3X^2, b = 1 + 2X − X^2

$$\mathrm{a} + \mathrm{b} = 3 + \mathrm{X} + 2X^2$$
$$\mathrm{a} * \mathrm{b} = (2 - \mathrm{X} + 3X^2) * (1 + 2X = X^2)$$
$$= 2 + 4\mathrm{X} - 2X^2 - \mathrm{X} - 2X^2 + X^3 + 3X^2 + 6X^3 - 3X^4$$

N = 3; hence the polynomial cannot have powers of X more than 2, so we have to truncate powers of X higher than 2 with the following rules:

$$X^4 \; by \; X$$
$$X^3 \; by \; X^0 = 1$$

Hence,

$$\mathrm{a} * \mathrm{b} = 2 + 4X - 2X^2 - X - 2X^2 + 1 + 3X^2 + 6 - 3X$$
$$= (9 - X^2)$$

The distributive law also holds for the polynomials

$$\mathrm{a} * (\mathrm{b} + \mathrm{c}) = \mathrm{a} * \mathrm{b} + \mathrm{a} * \mathrm{c}$$

The inclusion of the above law makes the algebraic structure of polynomials into a ring, the Ring of Truncated Polynomials. This ring R is isomorphic to the quotient ring, $Z[X]/(X^{(N-1)})$.

Inverses in Truncated Polynomial Ring

The inverse modulo q of a polynomial a is a polynomial a^{-1} with the property:

$$\mathrm{a} * a^{-1} = 1(mod\ q)$$

Example:

$$\mathrm{N} = 7, \quad \text{and} \quad \mathrm{q} = 11$$

$$\mathrm{a} = 3 + 2X^2 - 3X^4 + X^6$$

then,

$$a^{-1} = 2 + 4X + 2X^2 + 4X^3 - 4X^4 + 2X^5 - 2X^6$$
$$= (3 + 2X^2 - 3X^4 + X^6)*$$
$$(2 + 4X + 2X^2 + 4X^3 - 4X^4 + 2X^5 - 2X^6)$$
$$= -10 + 22X - 22X^3 + 22X^6 = 1(\text{mod } 11)$$

NTRU Parameters and Keys

N—a polynomial in the ring R with degree N − 1, with N being a prime number:

Q—a large modulus to which the coefficient is reduced
P—a small modulus to which each coefficient is reduced
q and p are coprime
f—a polynomial that is a private key
g—a polynomial that is used to generate the public key h from f
NOTE: g (secret) is discarded later on.
H—a polynomial that is a public key
r—a random binding polynomial (discarded later on, but kept secret.
D—coefficient.

Key Generation

Consider a truncated polynomial ring with a degree at most N − 1:

$$a_0 + a_1X + a_2X^2 \ldots\ldots\ldots a_{N-1}X^{(N-1)}$$

1 Choose two small polynomials f and g in the ring R; polynomial f must have an inverse.
2 The inverse of f modulo q and the inverse of f modulo p are computed.
3 $F_q = f^{-1}(mod\ q)$ *and* $F_p = f^{-1}(mod\ p)$
4 $f * F_q = 1(mod\ q)$ *and* $f * F_p = 1(mod\ p)$
5 Compute $h = p*(F_q*g)$ mod q.
6 Alice's private key: a pair of polynomials f and F_p
7 Alice's public key: the polynomial h

Public parameters (N, p, q, d) = (7, 3, 41, 2).
Alice chooses: $f(x) = X^6 - X^4 + X^3 + X^2 - 1$

$$g(x) = X^6 + X^4 - X^2 - X$$

$$F_q(x) = f^{-1}(X) - 1(mod\ q) = 8X^6 + 26X^5 + 31X^4 + 21X^3 + 40X^2 + 2X + 37\ (mod\ 41)$$

Private Key

$$F_p(x) = f^{-1}(X) - 1(mod\ q)$$
$$= X^6 + 2X^5 + X^3 + X^2 + X + 1\ (mod\ 3)$$

Public Key

$$h(x) = p * (F_q) * g(\text{mod q})$$
$$= 20X^6 + 40X^5 + 2X^4 + 38X^3 + 8X^2 + 26X + 30\ (mod\ 41)$$

NTRU Encryption

Alice has a message to transmit:

1. Puts the message in the form of polynomial m whose coefficient is chosen modulo p between −p/2 and p/2 (centered lift).
2. Randomly chooses another small polynomial r (to obscure the message).
3. Computes the encrypted message:

$$e = r * h + m(\text{modulo q})$$

Example of NTRU Encryption

Alice decides to send Bob the message:

$$m(X) = -X^5 + X^3 + X^2 - X^1 + 1$$

using the random key $r(x) = X^6 - X^5 + X^1 - 1$

$$e = r * h + m\ (\text{modulo q})$$

$$e(x) \equiv 31X^6 + 19X^5 + 4X^4 + 2X^3 + 40X^2 + 3X + 25\ (\text{mod } 41)$$

$$(N, p, q, d) = (7, 3, 41, 2)$$

NTRU Decryption

Bob receives a message e from Alice and would like to decrypt it.

Using his private polynomial f, he computes a polynomial

$$A = f * e(\text{mod q}).$$

Bob needs to choose coefficients that lie in an interval of length q. He computes the polynomial b = a(mod p). Bob reduces each of the coefficients of a modulo p. Bob uses the other private polynomial F_p to compute c = F_p*b (modulo p), which is the original message of Alice.

Example of NTRU Decryption

$$a = f * e(\text{mod } q)$$

Bob computes $a \equiv X^6 + 10X^5 + 33X^4 + 40X^3 + 40X^2 + X + 40 \ (\text{mod } 41)$

Bob then center lifts modulo q to obtain

$$b = a(\text{mod } p) = X^6 + 10X^5 - 8X^4 - X^3 - X^2 + X - 1 \ (\text{mod } 3)$$

Bob reduces a(x) modulo p and computes

$$c = F_p(x) * b(x) \equiv 2X^5 + X^3 + X^2 + 2X + 1(\text{mod } 3)$$

Center lifting modulo p retrieves Alice's plaintext

$$m(x) = -X^5 + X^3 + X^2 - X^1 + 1$$
$$(N, p, q, d) = (7, 3, 41, 2)$$

Why Does NTRU Work?

$$a = f * e(\text{mod } q) = f * (r * h + m) \ (\text{mod } q)$$
$$= f * (r * pF_q * g + m)(mod\ q) = pr * g + f * m(\text{mod } q)$$

$$b = a = f * m(\text{mod } p)$$

$$c = F_p * b = F_p * f * m = m(mod\ p)$$

$$\text{NTRU167} \equiv \text{ECC112} \equiv \text{RSA512}$$

$$\text{NTRU263} \equiv \text{ECC168} \equiv \text{RSA1024}$$

$$\text{NTRU503} \equiv \text{ECC196} \equiv \text{RSA2048}$$

Underlying every public-key cryptosystem lurks an extremely difficult mathematical problem waiting to be solved. There is no direct proof that breaking a cryptosystem is equivalent to solving the mathematical problem. Below we list the public-key cryptosystem and the corresponding mathematical problem.

RSA	Integer Factorization Problem
Diffe-Hellman	Discrete Logarithm Problem in F_q^*
Elliptic Curve Cryptography	Discrete Logarithm Problem on an Elliptic Curve
Lattices	SVP and CVP

3. SUMMARY

In this chapter, we reviewed aspects of advanced data encryption security: number theory, group theory, and finite fields relevant to public-key cryptography, as well as advanced data encryption security features (see checklist: An Agenda for Action for Implementing Advanced Data Encryption Security Features). The security of public-key cryptography is determined by what is known as the discrete logarithm problem (DLP), and we gave an example of DLP based on the elliptic curve. In the final section of this chapter, we presented public-key cryptography based on lattice theory—known as the NTRU cryptosystem.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Generation of a key in public-key cryptography involves exponentiation modulo a given modulus.
2. True or False? The order of a finite group is the number of elements in the group H.
3. True or False? In the multiplicative group, H = $<Z_{n^*}$, x$>$; when the order of an element is the same as $\phi(n)$, then that element is called the primitive root of the group.
4. True or False? A group H is said to be finite if the number of elements in the set H is finite.
5. True or False? The set of integers Z is a group under addition (+); that is (Z, +) is a group with identity e = 0, and inverse of an element a is (− a).

An Agenda for Action for Implementing Advanced Data Encryption Security Features

Please see the following advanced data encryption security features checklist that needs to be implemented in your organization (check all tasks completed):

Core Advanced Data Encryption Security Functionality

_____1. Hard Drive Encryption.
_____2. Saved Files.
_____3. Temporary Files.
_____4. Page Files.
_____5. Deleted Files.
_____6. Secure File Deletion.
_____7. Registry or Operating System Boot Files.
_____8. Unused Sectors.
_____9. Hidden Partitions.
_____10. Hibernation Mode.
_____11. Logout/Lockout.
_____12. Nonmagnetic Drives.
_____13. Removable Drives.
_____14. Data Recovery by Administrator.

Conformance to Protocol Standards

_____15. Password Management/Recovery (Admin).
_____16. PKI Authentication.
_____17. Multifactor Authentication.
_____18. Revocation of Access.

PKI Standards

_____19. X.509 Certificates.
_____20. LDAP Repository.
_____21. Certificate Revocation.
_____22. Cryptographic Algorithms.

Cryptographic Standards

Encryption Algorithms

_____23. Advanced Encryption Standard (AES).
_____24. Triple-Data Encryption Standard (3DES).

Key Establishment Algorithms

_____25. Rivest, Shamir, Adleman (RSA).
_____26. Other algorithms based on exponentiation of finite fields.
_____27. Key Exchange Algorithm (KEA).
_____28. Elliptic Curve algorithms.

Digital Signature Algorithms

_____29. RSA.
_____30. Digital Signature Algorithm (DSA).
_____31. Other algorithms based on exponentiation of finite fields.
_____32. Elliptic Curve Digital Signature Algorithm (ECDSA).

Hashing Algorithms

_____33. SHA-1.
_____34. SHA-224.
_____35. SHA-256.
_____36. SHA-384.
_____37. SHA-512.

Assurance Standards

_____38. FIPS 140-1.
_____39. FIPS 140-2.

Cryptographic Algorithm Validation Program

_____40. Cryptographic Module Validated.

Configurability

_____41. Changeable Default Values.
_____42. Multiple Users.
_____43. Different User Access Rights.
_____44. Transaction Logging.
_____45. Log Integrity.
_____46. Log Centralization.
_____47. Security Alerts.

Usability

_____48. Configuration by Users.
_____49. Authentication by Users.
_____50. Interruptions during Initial Encryption Process.
_____51. Computer use during Initial Encryption Process.
_____52. Software/Hardware Compatibility.
_____53. Maintenance by Administrators.
_____54. Administrator Recovery.
_____55. Third Party Recovery.

Manageability

_____56. Central Management.
_____57. Remote Management.
_____58. Unattended Reboot.
_____59. Authentication of Management Traffic.
_____60. Encryption of Management Traffic.

Scalability

_____61. Degree of Scalability.

Multiple Choice

1. A subgroup of a group G is a nonempty subset H of G, which itself is a group under the same operations as that of:
A. R
B. I
C. N
D. E
E. G

2. What group is said to be cyclic if there exists an element $a \in G$ such that for any $b \in G$, and $i \geq 0$, $b = a^i$?
A. O
B. W

C. S
D. G
E. A

3. Let ________ be a nonempty set with two binary operations addition (+), and multiplication (*).
   A. R
   B. I
   C. W
   D. C
   E. S
4. If the nonzero elements of a ring form a group under multiplication, then the ring is called a:
   A. field
   B. denial-of-service attack
   C. venyo
   D. port traffic
   E. taps
5. Construction of finite fields and computations in finite fields are based on:
   A. systems security plan
   B. polynomial computations
   C. denying service
   D. decision making
   E. URL lists

EXERCISE

Foreword

The second edition of the *Computer and Information Security Handbook* goes well beyond the classic reference status of the first edition. The second edition provides expanded coverage of security for new technologies and textbook elements including review questions, exercises, hands-on projects, and case projects for individual students and for groups of students studying in a cohort environment.

The expanded technology coverage includes cloud computing, optical networks, cryptography, and intrusion detection and prevention. The expanded security practices covered includes ethical hacking, cyber and systems forensics, cyber attack and cyber warfare countermeasures.

The expansion of technology and methods in the second edition of the *Computer and Information Security Handbook* provides the security professional and security students with a more comprehensive reference. The second edition is an essential addition to the security libraries or corporations, universities and colleges, as well as all security practitioners regardless of their level of expertise.

The inclusion of textbook elements makes the second edition of the *Computer and Information Security Handbook* a viable and attractive textbook for technical schools, colleges, and university courses at all levels. In that security issues and technology are virtually universal, the second edition will be usable in classrooms around the world.

John Vacca, and his team of computer and information security experts have assembled a wealth of knowledge along with practical actionable methods to address a wide range of security issues. The second edition of the *Computer and Information Security Handbook* will be a powerful tool in the hands of those who are working to protect and defend computer and information assets around the world.

Michael Erbschloe
Information Security Consultant
Michael Erbschloe teaches information security courses at Webster University in St. Louis, Missouri.

Preface

The second edition of this comprehensive handbook serves as a professional reference to provide today's most complete and concise view of computer security and privacy available in one volume. It offers in-depth coverage of computer security theory, technology, and practice as they relate to established technologies as well as recent advancements. It explores practical solutions to a wide range of security issues. Individual chapters are authored by leading experts in the field and address the immediate and long-term challenges in the authors' respective areas of expertise.

The primary audience for this handbook consists of researchers and practitioners in industry and academia as well as security technologists and engineers working with or interested in computer security. This comprehensive reference will also be of value to students in upper-division undergraduate and graduate-level courses in computer security.

ORGANIZATION OF THIS BOOK

The book is organized into ten parts composed of 70 contributed chapters by leading experts in their fields, as well as 12 appendices, including an extensive glossary (available online) of computer security terms and acronyms.

Part 1: Overview of System and Network Security: A Comprehensive Introduction

Part 1 discusses how to build a secure organization; generate cryptography; how to detect system intrusions; how to prevent system intrusions; secure cloud computing systems; fault tolerance and resilience in cloud computing environments; how to secure web applications, services and servers; UNIX and Linux security; eliminate the security weakness of Linux and UNIX Operating systems; Internet and intranet security; the botnet problem; LAN security; wireless network security; wireless sensor network security; cellular network security, RFID security; optical network security; and, optical wireless network security. For instance:

Chapter 1, "Building a Secure Organization," sets the stage for the rest of the book by presenting insight into where to start building a secure organization.

Chapter 2, "A Cryptography Primer," provides an overview of cryptography. It shows how communications may be encrypted and transmitted.

Chapter 3, "Detecting System Intrusions," describes the characteristics of the DSI technologies and provides recommendations for designing, implementing, configuring, securing, monitoring, and maintaining them.

Chapter 4, "Preventing System Intrusions," discusses how to prevent system intrusions and where an unauthorized penetration of a computer in your enterprise or an address in your assigned domain can occur.

Chapter 5, "Guarding Against Network Intrusions," shows how to guard against network intrusions by understanding the variety of attacks, from exploits to malware and social engineering.

Chapter 6, "Securing Cloud Computing Systems," discusses various cloud computing environments and methods to make them more secure for hosting companies and their customers.

Chapter 7, "Fault Tolerance and Resilience in Cloud Computing Environments," focuses on characterizing the recurrent failures in a typical Cloud computing environment, analyzing the effects of failures on user's applications, and surveying fault tolerance solutions corresponding to each class of failures.

Chapter 8, "Securing Web Applications, Services and Servers," provides a general overview of the breadth of web service security, an introduction to the subject area, and guides the reader to sources with deeper information.

Chapter 9, "UNIX and Linux Security," discusses how to scan for vulnerabilities; reduce denial-of-service (DoS) attacks; deploy firewalls to control network traffic; and build network firewalls.

Chapter 10, "Eliminating the Security Weakness of Linux and UNIX Operating Systems," presents an introduction to securing UNIX in general and Linux in particular, providing some historical context and describing some fundamental aspects of the secure operating system architecture.

Chapter 11, "Internet Security," shows you how cryptography can be used to address some of the security issues besetting communications protocols.

Chapter 12, "The Botnet Problem," describes the botnet threat and the countermeasures available to network security professionals.

Chapter 13, "Intranet Security," covers internal security strategies and tactics; external security strategies and tactics; network access security; and Kerberos.

Chapter 14, "Local Area Network Security," discusses network design and security deployment as well as ongoing management and auditing.

Chapter 15, "Wireless Network Security," presents an overview of wireless network security technology; how to design wireless network security and plan for wireless network security; how to install, deploy, and maintain wireless network security; information warfare countermeasures: the wireless network security solution; and wireless network security solutions and future directions.

Chapter 16, "Wireless Sensor Network Security," helps organizations design, implement and evaluate wireless sensor intrusion detection systems, which aim at transferring the computational load of the operation from the sensors to the base station.

Chapter 17, "Cellular Network Security," addresses the security of the cellular network; educates readers on the current state of security of the network and its vulnerabilities; outlines the cellular network specific attack taxonomy, also called *three-dimensional attack taxonomy*; discusses the vulnerability assessment tools for cellular networks; and provides insights into why the network is so vulnerable and why securing it can prevent communication outages during emergencies.

Chapter 18, "RFID Security," describes the RFID tags and RFID reader and back-end database in detail.

Chapter 19, "*Optical Network Security*," presents an analysis of attack and protection problems in optical networks. It also proposes a conceptual framework for modeling attack problems and protection schemes for optical networks.

Chapter 20, "*Optical Wireless Network Security*," focuses on free space optics (FSO) and the security that has been developed to protect its transmissions, as well as an overview of the basic technology.

Part 2: Managing Information Security

Part 2 discusses how to protect mission-critical systems; deploy security management systems, policy-driven system management, IT security management, online identity and user management services, intrusion detection and prevention systems, TCP/IP packet analysis, intruder's genesis, firewalls, penetration testing; conduct vulnerability assessments and security metrics. For instance:

Chapter 21, "Information Security Essentials for IT Managers: Protecting Mission-Critical Systems," discusses how security goes beyond technical controls and encompasses people, technology, policy, and operations in a way that few other business objectives do.

Chapter 22, "Security Management Systems," examines documentation requirements and maintaining an effective security system as well as conducting assessments.

Chapter 23, "Policy-driven System Management," focuses particularly on PBM's use for securing computing systems according to high-level security goals.

Chapter 24, "Information Technology Security Management," discusses the processes that are supported with enabling organizational structure and technology to protect an organization's information technology operations and IT assets against internal and external threats, intentional or otherwise.

Chapter 25, "Online Identity and User Management Services," presents the evolution of identity management requirements. It also surveys how the most advanced identity management technologies fulfill present-day requirements. It discusses how mobility can be achieved in the field of identity management in an ambient intelligent/ubiquitous computing world.

Chapter 26, "Intrusion Detection and Prevention Systems," discusses the nature of computer system intrusions, the people who commit these attacks, and the various technologies that can be utilized to detect and prevent them.

Chapter 27, "TCP/IP Packet Analysis," discusses how TCP/IP packets are constructed, and analyzed to interpret the applications that use the TCP/IP stack.

Chapter 28, "The Enemy (The Intruder's Genesis)," discusses process of creating a formal set of governance to define the CYBERSECURITY, and course of actions to be taken to defend against the CYBERATTACKS.

Chapter 29, "Firewalls," provides an overview of firewalls: policies, designs, features, and configurations. Of course, technology is always changing, and network firewalls are no exception. However, the intent of this chapter is to describe aspects of network firewalls that tend to endure over time.

Chapter 30, "Penetration Testing," describes how testing differs from an actual "hacker attack" as well as some of the ways penetration tests are conducted, how they're controlled, and what organizations might look for when choosing a company to conduct a penetration test for them.

Chapter 31, "What Is Vulnerability Assessment?" covers the fundamentals: defining vulnerability, exploit, threat, and risk; analyzing vulnerabilities and exploits; and configuring scanners. It also shows you how to generate reports, assess risks in a changing environment, and manage vulnerabilities.

Chapter 32, "Security Metrics: An Introduction and Literature Review" describes the need for security metrics, followed by a discussion of the nature of security metrics, including what makes a good security metric, what security metrics have been used in the past, and how security metrics can be scientifically based.

Part 3: Cyber, Network, and Systems Forensics Security and Assurance

Part 3 discusses how to implement cyber forensics; cyber forensics and incidence response; how to secure e-discovery, and network forensics. For instance:

Chapter 33, "Cyber Forensics," is intended to provide an in-depth familiarization with computer forensics as a career, a job, and a science. It will help you avoid mistakes and find your way through the many aspects of this diverse and rewarding field.

Chapter 34, "Cyber Forensics And Incidence Response," discusses the steps and methods to respond to incidents and conduct cyber forensics investigations.

Chapter 35, "Securing e-Discovery," explains EDRM from an industry insider perspective; collates issues of performance, urgency, accuracy, risk, and security to a zoned model that underpins the EDRM; explains the very real need for organizations to secure certain operations internally; provides examples through real-world experiences of flawed discovery, and what should have been done differently; and, discusses how security *from* the information as well as security *of* it, plays a critical role throughout much of the EDRM.

Chapter 36, "Network Forensics," helps you determine the path from a victimized network or system through any intermediate systems and communication pathways, back to the point of attack origination or the person who should be held accountable.

Part 4: Encryption Technology

Part 4 discusses how to implement data encryption, satellite encryption, public key infrastructure, and instant-messaging security. For instance:

Chapter 37, "Data Encryption," is about the role played by cryptographic technology in data security.

Chapter 38, "Satellite Encryption," proposes a method that enhances and complements satellite encryption's role in securing the information society. It also covers satellite encryption policy instruments; implementing satellite encryption; misuse of satellite encryption technology; and results and future directions.

Chapter 39, "Public Key Infrastructure," explains the cryptographic background that forms the foundation of PKI systems; the mechanics of the X.509 PKI system (as elaborated by the Internet Engineering Task Force); the practical issues surrounding the implementation of PKI systems; a number of alternative PKI standards; and alternative cryptographic strategies for solving the problem of secure public key distribution.

Chapter 40, "Instant-Messaging Security," helps you develop an IM security plan, keep it current, and make sure it makes a difference.

Part 5: Privacy and Access Management

Part 5 discusses Internet privacy, personal privacy policies, virtual private networks, identity theft, and VoIP security. For instance:

Chapter 42, "Privacy On The Internet," addresses the privacy issues in the digital society from various points of view, investigating the different aspects related to the notion of privacy and the debate that the intricate essence of privacy has stimulated; the most common privacy threats and the possible economic aspects that may influence the way privacy is (and especially is not currently) managed in most firms; the efforts in the computer science community to face privacy threats, especially in the context of mobile and database systems; and the network-based technologies available to date to provide anonymity when communicating over a private network.

Chapter 43, "Privacy-enhancing Technologies," provides an overview to the area of Privacy-enhancing Technologies (PETs), which help to protect privacy by technically enforcing legal privacy principles.

Chapter 44, "Personal Privacy Policies," begins with the derivation of policy content based on privacy legislation, followed by a description of how a personal privacy policy may be constructed semiautomatically. It then shows how to additionally specify policies so that negative unexpected outcomes can be avoided. Finally, it describes the author's Privacy Management Model, which explains how to use personal privacy policies to protect privacy, including what is meant by a "match" of consumer and service provider policies and how nonmatches can be resolved through negotiation.

Chapter 45, "Detection Of Conflicts In Security Policies," identifies the common approaches to the identification of security conflicts considering three relevant scenarios: access control policies, policy execution, and network protection. The chapter focuses on the detection of the conflicts.

Chapter 46, "Supporting User Privacy Preferences in Digital Interactions," describes solutions supporting both client privacy preferences, and server disclosure policies.

Chapter 47, "Privacy and Security in Environmental Monitoring Systems: Issues and Solutions," identifies the main security and privacy issues characterizing the environmental data as well as the environmental monitoring infrastructures

Chapter 48, "Virtual Private Networks," covers VPN scenarios, VPN comparisons, and information assurance requirements. It also covers building VPN tunnels; applying cryptographic protection; implementing IP security; and deploying virtual private networks.

Chapter 49, "Identity Theft," describes the importance of understanding the human factor of ID theft security and details the findings from a study on deceit.

Chapter 50, "VoIP Security," deals with the attacks targeted toward a specific host and issues related to social engineering.

Part 6: Storage Security

Part 6 covers storage area network (SAN) security and risk management. For instance:

Chapter 51, "SAN Security," describes the following components: protection rings; security and protection; restricting access to storage; access control lists (ACLs) and policies; port blocks and port prohibits; and zoning and isolating resources.

Chapter 52, "Storage Area Networking Security Devices," covers all the issues and security concerns related to SAN security.

Chapter 53, "Risk Management," discusses physical security threats, environmental threats, and incident response.

Part 7: Physical Security

Part 7 discusses physical security essentials, disaster recovery, biometrics, homeland security, and Cyber warfare. For instance:

Chapter 54, "Physical Security Essentials," is concerned with physical security and some overlapping areas of premises security. It also looks at physical security threats and then considers physical security prevention measures.

Chapter 55, "Disaster Recovery," provides insight to the job of DR, and provide a framework of what is necessary to achieve a successful Disaster Recovery plan.

Chapter 56, "Biometrics," discusses the different types of biometrics technology and verification systems and how the following work: biometrics eye analysis technology; biometrics facial recognition technology; facial thermal imaging; biometrics finger-scanning analysis technology; biometrics geometry analysis technology; biometrics verification technology; and privacy-enhanced, biometrics-based verification/authentication as well as biometrics solutions and future directions.

Chapter 57, "Homeland Security," describes some principle provisions of U.S. homeland security-related laws and Presidential directives. It gives the organizational changes that were initiated to support homeland security in the United States. The chapter highlights the 9/11 Commission that Congress charted to provide a full account of the circumstances surrounding the 2001 terrorist attacks and to develop recommendations for corrective measures that could be taken to prevent future acts of terrorism. It also details the Intelligence Reform and Terrorism Prevention Act of 2004 and the Implementation of the 9/11 Commission Recommendations Act of 2007.

Chapter 58, "Cyber Warfare," defines cyber warfare (CW) and discusses its most common tactics, weapons, and tools as well as comparing CW terrorism with conventional warfare and addressing the issues of liability and the available legal remedies under international law.

Part 8: Practical Security

Part 8 discusses *system security*, how to secure *the infrastructure*, *access controls*, assessments and audits and fundamentals of cryptography. For instance:

Chapter 59, "System Security," shows you how to protect your information from harm, and also ways to make your data readily available for access to an intended audience of users.

Chapter 60, "Securing the Infrastructure," focuses on how security is presented to protect the infrastructure. Smart grid cybersecurity in this chapter, also addresses not only deliberate attacks, such as from disgruntled employees, industrial espionage, and terrorists; but, also inadvertent compromises of the information infrastructure due to user errors, equipment failures, and natural disasters.

Chapter 61, "Access Controls," endeavours to inform the reader about the different types of access controls that are being used, and describes the pros and cons they might have.

Chapter 62, "Assessments and Audits," presents the basic technical aspects of conducting information security assessments and audits. It presents technical testing and examination methods and techniques that an organization might use as part of an assessment and audit, and offers insights to assessors on their execution and the potential impact they may have on systems and networks.

Chapter 63, "Fundamentals of Cryptography," discusses how information security is the discipline that provides protection of information from intrusion and accidental or incidental loss. It also provides a framework for the protection of information from unauthorized use, copying, distribution, or destruction of data.

Part 9: Advanced Security

Part 9 discusses security through diversity, online reputation, content filtering, and data loss protection. For instance:

Chapter 64, "Security Through Diversity," covers some of the industry trends in adopting diversity in hardware, software, and application deployments. This chapter also covers the risks of uniformity, conformity, and the

ubiquitous impact of adopting standard organizational principals without the consideration of security.

Chapter 65, "Online e-Reputation Management Services," discusses the general understanding of the human notion of reputation. It explains how this concept of reputation fits into computer security. The chapter presents the state of the art of attack-resistant reputation computation. It also gives an overview of the current market of online reputation services. The chapter concludes by underlining the need to standardize online reputation for increased adoption and robustness.

Chapter 66, "Content Filtering," examines the many benefits and justifications of Web-based content filtering such as legal liability risk reduction, productivity gains, and bandwidth usage. It also explores the downside and unintended consequences and risks that improperly deployed or misconfigured systems create. The chapter also looks into methods to subvert and bypass these systems and the reasons behind them.

Chapter 67, "Data Loss Protection," introduces the reader to a baseline understanding of how to investigate and evaluate DLP applications in the market today.

Chapter 68, "Satellite Cyber Attack Search and Destroy," discusses satellite cyber attacks with regards to hacking, interference and jamming.

Chapter 69, "Verifiable Voting Systems," emphasizes the challenge to reconcile the secrecy of the ballot, with demonstrable correctness of the result.

Chapter 70, "Advanced Data Encryption," explores advanced data encryption algorithms.

SUPPLEMENTAL MATERIALS

Instructor materials including a glossary, lecture slides, figures from the text, exercise solutions, and sample syllabi are available at: store.elsevier.com/product.jsp?isbn=9780123943972 (click the "Resources" tab at the bottom of the page)

Acknowledgments

There are many people whose efforts on this book have contributed to its successful completion. I owe each a debt of gratitude and want to take this opportunity to offer my sincere thanks.

A very special thanks to my publisher, Steve Elliot, without whose continued interest and support this book would not have been possible. Senior development editor Nate McFadden provided staunch support and encouragement when it was most needed. Thanks to my production project manager, Mohanambal Natarajan, whose fine work and attention to detail has been invaluable. Thanks also to my marketing manager, Todd Conly, whose efforts on this book have been greatly appreciated. Finally, thanks to all the other people at Morgan Kaufmann Publishers/Elsevier Science & Technology Books, whose many talents and skills are essential to a finished book.

Thanks to my wife, Bee Vacca, for her love, her help, and her understanding of my long work hours. Also, a very, very special thanks to Michael Erbschloe for writing the Foreword. Finally, I wish to thank all the following authors who contributed chapters that were necessary for the completion of this book: Claudio Agostino Ardagna, Jeffrey S. Bardin , Sanjay Bavisi, Stefan Berthold, Gerald Beuchelt, Rahul Bhaskar, Chiara Braghin, Albert Caballero, Professor Erdal Cayirci, Tom Chen, Hongbing Cheng, Lauren Collins, Marco Cremonini, Sam Curry, Christopher Day, Sabrina De Capitani Di Vimercati, Scott R. Ellis, Michael Erbschloe, Simone Fischer-Hbner, Sara Foresti, Errin W. Fulp, Anna Granova, Yong Guan, Cem Gurkok, Feng Hao, James T. Harmening, Markus Jakobsson, Ravi Jhawar, Almantas Kakareka, Bhushan Kapoor, Sokratis K. Katsikas, Dalia Khader, Larry Korba, Kameswari Kotapati, Thomas F. LaPorta, Jean Lencrenon, Peng Liu, Tewfiq El Maliki, John R. Mallery, Bill Mansoor, Luther Martin, John McDonald, John McGowan, Peter F. Nicoletti, Kevin Noble, Pramod Pandya, Harsh Kupwade Patil, Stefano Paraboschi, Thea Peacock, Ken Perkins, Vincenzo Piuri, Henrik Plate, Daniel Ramsbrock, Chunming Rong, Robert Rounsavall, Peter Ryan, Marco Santambrogio, Mario Santana, Steve Schneider, Jean-Marc Seigneur, Marco Slaviero, Daniel S. Soper, Terence Spies, William Stallings, Alex Tsow, Jesse Walker, Patrick J. Walsh, Xinyuan Wang, Michael A. West, Dan Wing, Zhe Zia, George O.M. Yee, Liang Yan, Gansen Zhao.

About the Editor

John Vacca is an information technology consultant, professional writer, editor, reviewer and internationally-known, best-selling author based in Pomeroy, Ohio. Since 1982, John has authored 72 *books* (some of his most recent books include):

- Identity Theft (Cybersafety) (*Publisher:* Chelsea House Pub (April 1, 2012)
- System Forensics, Investigation, And Response (*Publisher:* Jones & Bartlett Learning (September 24, 2010)
- Managing Information Security (*Publisher:* Syngress (an imprint of Elsevier Inc.) (March 29, 2010))
- Network and Systems Security (*Publisher:* Syngress (an imprint of Elsevier Inc.) (March 29, 2010))
- Computer and Information Security Handbook (*Publisher:* Morgan Kaufmann (an imprint of Elsevier Inc.) (June 2, 2009))
- Biometric Technologies and Verification Systems (*Publisher:* Elsevier Science & Technology Books (March 16, 2007))
- Practical Internet Security (Hardcover): (*Publisher:* Springer (October 18, 2006))
- Optical Networking Best Practices Handbook (Hardcover): (*Publisher*: Wiley-Interscience (November 28, 2006))
- Guide to Wireless Network Security (*Publisher:* Springer (August 19, 2006)
- Computer Forensics: Computer Crime Scene Investigation (With CD-ROM), 2nd Edition (*Publisher:* Charles River Media (May 26, 2005)

and, more than 600 articles in the *areas* of advanced storage, computer security and aerospace technology (copies of articles and books are available upon request). John was also a configuration management specialist, computer specialist, and the computer security official (CSO) for NASA's space station program (Freedom) and the International Space Station Program, from 1988 until his retirement from NASA in 1995. In addition, John is also an *independent online book reviewer*. Finally, John was one of the security consultants for the MGM movie titled: "AntiTrust," which was released on January 12, 2001. A detailed copy of my author bio can be viewed at URL: http://www.johnvacca.com. John can be reached at: john2164@windstream.net.

Contributors

Claudio Agostino Ardagna (Chapter 42), Professor, Dept. of Information Technology, University of Milan, Crema, Italy

Jeffrey Bardin (Chapter 51, 68), Chief Intelligence Strategist, Treadstone 71 LLC, Barre, MA 01005

Sanjay Bavisi (Chapter 30), President, EC-Council, Selangor, Malaysia

Stefan Berthold (Chapter 43), Tek. Lic., Karlstad University, Karlstad/Sweden

Gerald Beuchelt (Chapters 8, 9), Principal Software Systems Engineer, Bedford, MA 01803

Rahul Bhaskar (Chapter 24, 57), Professor, Department of Information Systems and Decision Sciences, California State University, Fullerton, California 92834

Chiara Braghin (Chapter 42), Professor, Dept. of Information Technology, University of Milan, Crema, Italy

Albert Caballero CISSP, GSEC (Chapter 21), Chief Technology Officer−CTO, Digital Era Group, LLC, Surfside, Fl. 33154

Professor Erdal Cayirci (Chapters 15, 18), Professor, University of Stavanger, N-4036 Stavanger, Norway

Thomas M. Chen (Chapter 5, 16, 50), Professor, Swansea University, Singleton Park, SA2 8PP, Wales, United Kingdom

Hongbing Cheng (Chapter 15, 18), Professor, University of Stavanger, Norway

Lauren Collins (Chapters 19, 55, 59, 60, 61, 62), Senior Systems Engineer, kCura Corporation, Chicago, IL 60604

Marco Slaviero (Chapters 58), Security Analyst, SensePost Pty Ltd, Pretoria, South Africa

Daniel S. Soper (Chapter 38), Professor, Information and Decision Sciences Department, Mihaylo College of Business and Economics, California State University, Fullerton, California 92834-6848

Terence Spies (Chapter 39), Chief Technology Officer// vice president of engineering, Voltage Security, Inc., Palo Alto, California 94304

William Stallings (Chapter 54), Independent consultant, Brewster Massachusetts 02631

Alex Tsow (Chapter 49), The MITRE Corporation, Mclean, Virginia 22102

Jesse Walker (Chapter 11), Principal Engineer, Intel Corporation, Hillsboro, Oregon 97124

Patrick J. Walsh (Chapter 5), eSoft Inc., Broomfield, Colorado 80021

Xinyuan Wang (Chapter 12), Professor, Department of Computer Science, George Mason University, Fairfax, Virginia 22030

Michael West (Chapter 4), Senior technical writer, Truestone Maritime Operations Martinez, California 94553

Dan Wing (Chapter 50), Distinguished Engineer, Cisco Systems, Inc., San Jose, CA 95123

Zhe Xia (Chapters 69), Professor, University of Surrey, Guildford, Surrey, GU2 7XH

George O.M. Yee (Chapter 32, 44), Adjunct Research Professor, Carleton University, Ottawa, ON, Canada K1G 5N7

Liang Yan (Chapter 15, 18), Professor, University of Stavanger, Norway

Gansen Zhao (Chapter 15, 18), Professor, South China Normal University, Guangzhou 510631, P.R.China

Dedication

This book is dedicated to my wife, Bee.

Appendix eL

Glossary

AAA Administration, authorization, and authentication.

Access A specific type of interaction between a subject and an object that results in the flow of information from one to the other. The capability and opportunity to gain knowledge of, or to alter information or materials including the ability and means to communicate with (i.e., input or receive output), or otherwise make use of any information, resource, or component in a computer system.

Access Control The process of limiting access to the resources of a system to only authorized persons, programs, processes, or other systems. Synonymous with controlled access and limited access. Requires that access to information resources be controlled by or for the target system. In the context of network security, access control is the ability to limit and control the access to host systems and applications via communications links. To achieve this control, each entity trying to gain access must first be identified, or authenticated, so that access rights can be tailored to the individual.

Accreditation The written formal management decision to approve and authorize an organization to operate a classified information system (IS) to process, store, transfer, or provide access to classified information.

Accreditation/Approval The official management authorization for operation of an MIS. It provides a formal declaration by an Accrediting Authority that a computer system is approved to operate in a particular security mode using a prescribed set of safeguards. Accreditation is based on the certification process as well as other management considerations. An accreditation statement affixes security responsibility with the Accrediting Authority and shows that proper care has been taken for security.

Activities An assessment object that includes specific protectionrelated pursuits or actions supporting an information system that involve people (conducting system backup operations, monitoring network traffic).

Adequate Security Security commensurate with the risk and magnitude of the harm resulting from the loss, misuse, or unauthorized access to or modification of information. This includes assuring that systems and applications used by the agency operate effectively and provide appropriate confidentiality, integrity, and availability, through the use of cost-effective management, personnel, operational and technical controls.

ADP Automatic Data Processing. See also: Management Information System.

AES Advanced Encryption Standard.

Agency See: *Executive Agency*.

Agent A host-based intrusion detection and prevention program that monitors and analyzes activity and may also perform prevention actions.

Alert A notification of an important observed event.

Anomaly-Based Detection The process of comparing definitions of what activity is considered normal against observed events to identify significant deviations.

Antivirus Software A program that monitors a computer or network to identify all major types of malware and prevent or contain malware incidents.

Application A software organization of related functions, or series of interdependent or closely related programs, that when executed accomplish a specified objective or set of user requirements. See also: Major Application, Process.

Application-Based Intrusion Detection and Prevention System A host-based intrusion detection and prevention system that performs monitoring for a specific application service only, such as a Web server program or a database server program.

Application Control The ability for next generation content filter gateways to inspect the application and determine its intention and block accordingly.

Application Layer The seventh layer of the Open Systems Interconnection (OSI) model. The point where the user application interfaces with the protocols to transfer data across the network.

Application Owner The official who has the responsibility to ensure that the program or programs, which make up the application accomplish the specified objective or set of user requirements established for that application, including appropriate security safeguards. See also: Process Owner.

Assessment See: *Security Control Assessment*.

Assessment Findings Assessment results produced by the application of an assessment procedure to a security control or control enhancement to achieve an assessment objective; the execution of a determination statement within an assessment procedure by an assessor that results in either a *satisfied* or *other than satisfied* condition.

Assessment Method One of three types of actions (examine, interview, test) taken by assessors in obtaining evidence during an assessment.

Assessment Object The item (specifications, mechanisms, activities, individuals) upon which an assessment method is applied during an assessment.

Assessment Objective A set of determination statements that expresses the desired outcome for the assessment of a security control or control enhancement.

Assessment Procedure A set of assessment *objectives* and an associated set of assessment *methods* and assessment *objects*.

Assessor See: *Security Control Assessor*.

Assurance The grounds for confidence that the set of intended security controls in an information system are effective in their application.

Assurance Case A structured set of arguments and a body of evidence showing that an information system satisfies specific claims with respect to a given quality attribute.

Attachment The blocking of certain types of file (executable programs).

Audit To conduct the independent review and examination of system records and activities.

Audit Capability The ability to recognize, record, store, and analyze information related to security-relevant activities on a system in such a way that the resulting records can be used to determine which activities occurred and which user was responsible for them.

Audit Trail A set of records that collectively provides documentary evidence of processing. It is used to aid in tracing from original transactions forward to related records and reports, and/or backwards from records and reports to their component source transactions.

Automated Information Systems (AIS) The infrastructure, organization, personnel, and components for the collection, processing, storage, transmission, display, dissemination, and disposition of information.

Automatic Data Processing (ADP) The assembly of computer hardware, firmware, and software used to categorize, sort, calculate, compute, summarize, store, retrieve, control, process, and/or protect data with a minimum of human intervention. ADP systems can include, but are not limited to, process control computers, embedded computer systems that perform general purpose computing functions, supercomputers, personal computers, intelligent terminals, offices automation systems (which includes standalone microprocessors, memory typewriters, and terminal connected to mainframes), firmware, and other implementations of MIS technologies as may be developed: they also include applications and operating system software. See also: Management Information System.

Authenticate/Authentication The process to verify the identity of a user, device, or other entity in a computer system, often as a prerequisite to allowing access to resources in a system. Also, a process used to verify that the origin of transmitted data is correctly identified, with assurance that the identity is not false. To establish the validity of a claimed identity.

Authenticated User A user who has accessed a MIS with a valid identifier and authentication combination.

Authenticator A method of authenticating a classified information system (IS) in the form of knowledge or possession (for example, password, token card, key).

Authenticity The property of being genuine and being able to be verified and trusted; confidence in the validity of a transmission, a message, or message originator. See: Authentication.

Authorization The privileges and permissions granted to an individual by a designated official to access or use a program, process, information, or system. These privileges are based on the individual's approval and need-to-know.

Authorization Boundary All components of an information system to be authorized for operation by an authorizing official and excludes separately authorized systems, to which the information system is connected.

Authorizing Official A senior (federal) official or executive with the authority to formally assume responsibility for operating an information system at an acceptable level of risk to organizational operations (including mission, functions, image, or reputation), organizational assets, individuals, other organizations, and the Nation.

Authorized Person A person who has the need-to-know for sensitive information in the performance of official duties and who has been granted authorized access at the required level. The responsibility for determining whether a prospective recipient is an authorized person rests with the person who has possession, knowledge, or control of the sensitive information involved, and not with the prospective recipient.

Authorizing Official Designated Representative An organizational official acting on behalf of an authorizing official in carrying out and coordinating the required activities associated with security authorization.

Availability The property of being accessible and usable upon demand by an authorized entity. Security constraints must make MIS services available to authorized users and unavailable to unauthorized users.

Availability of Data The state when data are in the place needed by the user, at the time the user needs them, and in the form needed by the user.

Backdoor A malicious program that listens for commands on a certain Transmission Control Protocol (TCP) or User Datagram Protocol (UDP) port.

Backup A copy of a program or data file for the purposes of protecting against loss if the original data becomes unavailable.

Backup and Restoration of Data The regular copying of data to separate media and the recovery from a loss of information.

Backup Operation A method of operations to complete essential tasks as identified by a risk analysis. These tasks would be employed following a disruption of the MIS and continue until the MIS is acceptably restored. See also: Contingency Plan, Disaster Recovery.

Bad Reputation Domains Sites that appear on one or more security industry blacklists for repeated bad behavior, including hosting malware and phishing sites, generating spam, or hosting content linked to by spam email.

Bandwidth A measure of spectrum (frequency) use or capacity. For instance, a voice transmission by telephone requires a

bandwidth of about 3000 cycles per second (3 KHz). A television channel occupies a bandwidth of 6 million cycles per second (6 MHz) in terrestrial Systems. In satellite-based systems a larger bandwidth of 17.5 to 72 MHz is used to spread or "dither" the television signal in order to prevent interference.

Basic Testing A test methodology that assumes no knowledge of the internal structure and implementation detail of the assessment object. Also known as black box testing.

Bent Pipe A description of a satellite communication architecture type in which data is transmitted to the satellite, which then sends it right back down again like a bent pipe. The only processing performed is retransmission of the signals.

Black Box Testing See: *Basic Testing*.

Blacklist A list of discrete entities, such as hosts or applications, that have been previously determined to be associated with malicious activity.

Blended Attack An instance of malware that uses multiple infection or transmission methods.

Blinding Generating network traffic that is likely to trigger many alerts in a short period of time, to conceal alerts triggered by a "real" attack performed simultaneously.

Boot Sector Virus A virus that infects the master boot record (MBR) of a hard drive or the boot sector of removable media, such as floppy diskettes.

Botnet Sites used by botnet herders for command and control of infected machines. Sites that known malware and spyware connects to for command and control by cyber criminals. These sites are differentiated from the Malcode category to enable reporting on potentially infected computers inside the network.

By URL Filtering based on the URL. This is a suitable for blocking Web sites or sections of Web sites.

C2 A level of security safeguard criteria. See also: Controlled Access Protection, TCSEC.

Capstone The U.S. Government's long-term project to develop a set of standards for publicly-available cryptography, as authorized by the Computer Security Act of 1987. The Capstone cryptographic system will consist of four major components and be contained on a single integrated circuit microchip that provides nonDoD data encryption for Sensitive But Unclassified information. It implements the Skipjack algorithm. See also: Clipper.

Certification The comprehensive analysis of the technical and nontechnical features, and other safeguards, to establish the extent to which a particular MIS meets a set of specified security requirements. Certification is part of the accreditation process and carries with it an implicit mandate for accreditation. See also: Accreditation.

Channel An information transfer path within a system or the mechanism by which the path is affected.

Channel Scanning Changing the channel being monitored by a wireless intrusion detection and prevention system.

CHAP Challenge Handshake Authentication Protocol developed by the IETF.

Chief Information Officer Agency official responsible for: (i) Providing advice and other assistance to the head of the executive agency and other senior management personnel of the agency to ensure that information technology is acquired and information resources are managed in a manner that is consistent with laws, Executive Orders, directives, policies, regulations, and priorities established by the head of the agency; (ii) Developing, maintaining, and facilitating the implementation of a sound and integrated information technology architecture for the agency; and (iii) Promoting the effective and efficient design and operation of all major information resources management processes for the agency, including improvements to work processes of the agency.

Chief Information Security Officer See: *Senior Agency Information Security Officer*.

Child Pornography Sites that promote, discuss or portray children in sexual acts and activity or the abuse of children. Pornographic sites that advertise or imply the depiction of underage models and that do not have a U.S.C. 2257 declaration on their main page. As of March 13, 2007, all sites categorized as child porn are actually saved into the URL Library in the Porn category and are automatically submitted to the Internet Watch Foundation for legal verification as child pornography (http://www.iwf.org.uk/). If the IWF agrees that a site and/or any of its hosted pages are child pornography, they add it those URLs to their master list. The master list is downloaded nightly and saved into the URL Library in the Child Porn category.

Cipher An algorithm for encryption or decryption. A cipher replaces a piece of information (an element of plain text) with another object, with the intent to conceal meaning. Typically, the replacement rule is governed by a secret key. See also: Decryption, Encryption.

Ciphertext Form of cryptography in which the *plaintext* is made unintelligible to anyone who intercepts it by a transformation of the information itself, based on some key.

CIO-Cyber Web Site Provides training modules for Cyber Security subjects.

Classification A systematic arrangement of information in groups or categories according to established criteria. In the interest of national security it is determined that the information requires a specific degree of protection against unauthorized disclosure together with a designation signifying that such a determination has been made.

Classified Distributive Information Network (CDIN) Any cable, wire, or other approved transmission media used for the clear text transmission of classified information in certain DOE access controlled environments. Excluded is any system used solely for the clear text transmission and reception of intrusion/fire alarm or control signaling.

Classified Information System (CIS) A discrete set of information resources organized for the collection, processing, maintenance, transmission, and dissemination of classified information, in accordance with defined procedures, whether automated or manual. Guidance Note: For the purposes of this document, an IS may be a standalone, single- or multiuser system or a network comprised of multiple systems and ancillary supporting communications devices, cabling, and equipment.

Classified Information Systems Security Plan (ISSP) The basic classified system protection document and evidence

that the proposed system, or update to an existing system, meets the specified protection requirements. The Classified ISSP describes the classified IS, any interconnections, and the security protections and countermeasures. This plan is used throughout the certification, approval, and accreditation process and serves for the lifetime of the classified system as the formal record of the system and its environment as approved for operation. It also serves as the basis for inspections of the system.

Classified Information Systems Security Program The Classified Information Systems Security Program provides for the protection of classified information on information systems at LANL.

Classified Information Systems Security Site Manager (ISSM) The manager responsible for the LANL Classified Information Systems Security Program.

Clear or Clearing (MIS Storage Media) The removal of sensitive data from MIS storage and other peripheral devices with storage capacity, at the end of a period of processing. It includes data removal in such a way that assures, proportional to data sensitivity, it may not be reconstructed using normal system capabilities, i.e., through the keyboard. See also: Object Reuse, Remanence.

Clipper Clipper is an encryption chip developed and sponsored by the U.S. government as part of the Capstone project. Announced by the White House in April 1993, Clipper was designed to balance competing concerns of federal law-enforcement agencies and private citizens by using escrowed encryption keys. See also: Capstone, Skipjack.

Collaborator A person not employed by the Laboratory who (1) is authorized to remotely access a LANL unclassified computer system located on the site or (2) uses a LANL system located off the site. Guidance note: A collaborator does not have an active Employee Information System record.

Commercial-off-the-Shelf (COTS) Products that are commercially available and can be utilized as generally marketed by the manufacturer.

Common Control A security control that is inherited by one or more organizational information systems. See: *Security ControlInheritance*.

Common Control Provider An organizational official responsible for the development, implementation, assessment, and monitoring of common controls (security controls inherited by information systems).

Communications Ground Station Telecommunications network nodes communicate through satellites, typically with small antennas and low-cost electronics at user facilities, and large antennas with more complex data handling facilities at key traffic hubs. Hub Earth stations are generally owned by satellite operators or specialized satellite network providers.

Communications Security (COMSEC) Measures and controls taken to deny unauthorized individuals information derived from telecommunications and to ensure the authenticity of such telecommunications. Communications security includes cryptosecurity, transmission security, emission security, and physical security of COMSEC material.

Compensating Security Controls The management, operational, and technical controls (safeguards or countermeasures) employed by an organization in lieu of the recommended controls in the baselines described in NIST Special Publication 800-53 and CNSS Instruction 1253, that provide equivalent or comparable protection for an information system.

Compiled Viruses A virus that has had its source code converted by a compiler program into a format that can be directly executed by an operating system.

Comprehensive Testing A test methodology that assumes explicit and substantial knowledge of the internal structure and implementation detail of the assessment object. Also known as white box testing.

Compromise The disclosure of sensitive information to persons not authorized access or having a need-to-know.

Computer Fraud and Abuse Act of 1986 This law makes it a crime to knowingly gain access to a federal government computer without authorization and to affect its operation.

Computer Security Technological and managerial procedures applied to MIS to ensure the availability, integrity, and confidentiality of information managed by the MIS. See also: Information Systems Security.

Computer Security Act of 1987 The law provides for improving the security and privacy of sensitive information in "federal computer systems"—"a computer system operated by a federal agency or other organization that processes information (using a computer system) on behalf of the federal government to accomplish a federal function."

Computer Security Incident Any event or condition having actual or potentially adverse effects on an information system. See the Cyber Security Handbook.

Computing, Communications, and Networking (CCN) Division Web Sites Describes network services and their use by system users.

Confidentiality The condition when designated information collected for approved purposes is not disseminated beyond a community of authorized knowers. It is distinguished from secrecy, which results from the intentional concealment or withholding of information. [OTA-TCT-606] Confidentiality refers to: 1) how data will be maintained and used by the organization that collected it; 2) what further uses will be made of it; and 3) when individuals will be required to consent to such uses. It includes the protection of data from passive attacks and requires that the information (in an MIS or transmitted) be accessible only for reading by authorized parties. Access can include printing, displaying, and other forms of disclosure, including simply revealing the existence of an object.

Configuration Management (CM) The management of changes made to an MIS hardware, software, firmware, documentation, tests, test fixtures, test documentation, communications interfaces, operating procedures, installation structures, and all changes there to throughout the development and operational life-cycle of the MIS.

Console A program that provides user and administrator interfaces to an intrusion detection and prevention system.

Contingency Plan The documented organized process for implementing emergency response, backup operations, and post-disaster recovery, maintained for an MIS as part of its

security program, to ensure the availability of critical assets (resources) and facilitate the continuity of operations in an emergency. See also: Disaster Recovery.

Contingency Planning The process of preparing a documented organized approach for emergency response, backup operations, and post-disaster recovery that will ensure the availability of critical MIS resources and facilitate the continuity of MIS operations in an emergency. See also: Contingency Plan, Disaster Recovery.

Control Segment Responsible for the operation of the overall satellite system, which includes platform control, payload control, and network control. The control segment consists of ground satellite control facilities, systems onboard the satellite and communications networks linking the control facilities.

Controlled Access Protection (C2) A category of safeguard criteria as defined in the Trusted Computer Security Evaluation Criteria (TCSEC). It includes identification and authentication, accountability, auditing, object reuse, and specific access restrictions to data. This is the minimum level of control for SBU information.

Controlled Unclassified Information A categorical designation that refers to unclassified information that does not meet the standards for National Security Classification under Executive Order 12958, as amended, but is (i) pertinent to the national interests of the United States or to the important interests of entities outside the federal government, and (ii) under law or policy requires protection from unauthorized disclosure, special handling safeguards, or prescribed limits on exchange or dissemination. Henceforth, the designation CUI replaces *Sensitive But Unclassified (SBU)*.

Conventional Encryption A form of cryptosystem in which encryption and decryption are performed using the same key. See also: Symmetric Encryption.

Cookie A small data file that holds information regarding the use of a particular Web site.

COTS See: Commercial-off-the-Shelf.

COTS Software Commercial-off the Shelf Software – software acquired by government contract through a commercial vendor. This software is a standard product, not developed by a vendor for a particular government project.

Countermeasures See: Security Safeguards.

Coverage An attribute associated with an assessment method that addresses the scope or breadth of the assessment objects included in the assessment (types of objects to be assessed and the number of objects to be assessed by type). The values for the coverage attribute, hierarchically from less coverage to more coverage, are basic, focused, and comprehensive.

Cracker See: Hacker.

Criminal Skills Sites that promote crime or illegal activity such as credit card number generation, illegal surveillance and murder. Sites which commercially sell surveillance equipment will not be saved. Sample sites: www.illegal-world.com, www.password-crackers.com, and www.spy-cam-surveillance-equipment.com

Critical Assets Those assets, which provide direct support to the organization's ability to sustain its mission. Assets are critical if their absence or unavailability would significantly degrade the ability of the organization to carry out its mission, and when the time that the organization can function without the asset is less than the time needed to replace the asset.

Critical Processing Any applications, which are so important to an organization, that little or no loss of availability is acceptable; critical processing must be defined carefully during disaster and contingency planning. See also: Critical Assets.

Cryptanalysis The branch of cryptology dealing with the breaking of a cipher to recover information, or forging encrypted information what will be accepted as authentic.

Cryptography The branch of cryptology dealing with the design of algorithms for encryption and decryption, intended to ensure the secrecy and/or authenticity of messages.

Cryptology The study of secure communications, which encompasses both cryptography and cryptanalysis.

Cybersecurity No formal, accepted definition of cybersecurity currently exists; however, the International Telecommunication Union recently approved ITU-T X.1205 "Overview of Cybersecurity." This document states "cybersecurity is the collection of tools, policies, security concepts, security safeguards, guidelines, risk management approaches, actions, training, best practices, assurance and technologies that can be used to protect the cyber environment and organization and user's assets. Organization and user's assets include connected computing devices, personnel, infrastructure, applications, services, telecommunications systems, and the totality of transmitted and/or stored information in the cyber environment. Cybersecurity strives to ensure the attainment and maintenance of the security properties of the organization and user's assets against relevant security risks in the cyber environment. The general security objectives comprise the following: availability, integrity, which may include authenticity and non-repudiation, and confidentiality."

Cyber Security Program The program mandated to ensure that the confidentiality, integrity, and availability of electronic data, networks and computer systems are maintained to include protecting data, networks and computing systems from unauthorized access, alteration, modification, disclosure, destruction, transmission, denial of service, subversion of security measures, and improper use.

Cyberspace *National Security Presidential Directive 54/ Homeland Security Presidential Directive 23* defines cyberspace as the interdependent network of information technology infrastructures, and include the Internet, telecommunications networks, computer systems, and embedded processors and controllers in critical industries. Common usage of the term also refers to the virtual environment of information and interactions between people.

DAC See: C2, Discretionary Access Control and TCSEC.

DASD (Direct Access Storage Device) A physical electromagnetic data storage unit used in larger computers. Usually these consist of cylindrical stacked multiunit assemblies, which have large capacity storage capabilities.

Data A representation of facts, concepts, information, or instructions suitable for communication, interpretation, or

processing. It is used as a plural noun meaning "facts or information" as in: *These data are described fully in the appendix,* or as a singular mass noun meaning "information" as in: *The data is entered into the computer.*

Database Server A repository for event information recorded by sensors, agents, or management servers.

Data Custodian The person who ensures that information is reviewed to determine if it is classified or sensitive unclassified. This person is responsible for generation, handling and protection, management, and destruction of the information. Guidance Note: An alternative name for the data custodian is classified information systems application owner.

Data Encryption Standard (DES) Data Encryption Standard is an encryption block cipher defined and endorsed by the U.S. government in 1977 as an official standard (FIPS PUB 59). Developed by IBM®, it has been extensively studied for over 15 years and is the most well known and widely used cryptosystem in the world. See also: Capstone, Clipper, RSA, Skipjack.

Data Integrity The state that exists when computerized data are the same as those that are in the source documents and have not been exposed to accidental or malicious alterations or destruction. It requires that the MIS assets and transmitted information be capable of modification only by authorized parties. Modification includes writing, changing, changing status, deleting, creating, and the delaying or replaying of transmitted messages. See also: Integrity, System Integrity.

Deciphering The translation of encrypted text or data (called ciphertext) into original text or data (called plaintext). See also: Decryption.

Decryption The translation of encrypted text or data (called ciphertext) into original text or data (called plaintext). See also: Deciphering.

Dedicated Security Mode An operational method when each user with direct or indirect individual access to a computer system, its peripherals, and remote terminals or hosts has a valid personnel security authorization and a valid need-to-know for all information contained within the system.

Dedicated System A system that is specifically and exclusively dedicated to and controlled for a specific mission, either for full time operation or a specified period of time. See also: Dedicated Security Mode.

Default A value or setting that a device or program automatically selects if you do not specify a substitute.

Degaussing Media Method to magnetically erase data from magnetic tape.

Denial of Service The prevention of authorized access to resources or the delaying of time-critical operations. Refers to the inability of a MIS system or any essential part to perform its designated mission, either by loss of, or degradation of operational capability.

Deny by Default A configuration for a firewall or router that denies all incoming and outgoing traffic that is not expressly permitted, such as unnecessary services that could be used to spread malware.

Department of Defense (DOD) Trusted Computer System Evaluation Criteria The National Computer Security Center (NCSC) criteria intended for use in the design and evaluation of systems that will process and/or store sensitive (or classified) data. This document contains a uniform set of basic requirements and evaluation classes used for assessing the degrees of assurance in the effectiveness of hardware and software security controls built in the design and evaluation of MIS. See also: C2, Orange Book, TCSEC.

Depth An attribute associated with an assessment method that addresses the rigor and level of detail associated with the application of the method. The values for the depth attribute, hierarchically from less depth to more depth, are basic, focused, and comprehensive.

DES See: Data Encryption Standard. See also: Capstone, Clipper, RSA, Skipjack.

Designated Accrediting Authority (DAA) A DOE official with the authority to formally grant approval for operating a classified information system; the person who determines the acceptability of the residual risk in a system that is prepared to process classified information and either accredits or denies operation of the system.

Designated Security Officer The person responsible to the designated high level manager for ensuring that security is provided for and implemented throughout the life-cycle of an MIS from the beginning of the system concept development phase through its design, development, operations, maintenance, and disposal.

Dial-up The service whereby a computer terminal can use the telephone to initiate and effect communication with a computer.

Digital Signature Standard DSS is the Digital Signature Standard, which specifies a Digital Signature Algorithm (DSA), and is part of the U.S. government's Capstone project. It was selected by NIST and NSA to be the digital authentication standard of the U.S. government, but has not yet been officially adopted. See also: Capstone, Clipper, RSA, Skipjack.

Disaster Recovery Plan The procedures to be followed should a disaster (fire, flood, etc.) occur. Disaster recovery plans may cover the computer center and other aspects of normal organizational functioning. See also: Contingency Plan.

Discretionary Access Control (DAC) A means of restricting access to objects based on the identity of subjects and/or groups to which they belong or on the possession of an authorization granting access to those objects. The controls are discretionary in the sense that a subject with a certain access permission is capable of passing that permission (perhaps indirectly) onto any other subject.

Discretionary access controls Controls that limit access to information on a system on an individual basis.

Discretionary processing Any computer work that can withstand interruption resulting from some disaster.

Disinfecting Removing malware from within a file.

Downlink The portion of a communications link used to transmit signals from a satellite to an Earth-based terminal (on land, ship, or aircraft).

DSS See: Capstone, Clipper, Digital Signature Standard, RSA, Skipjack.

Dubious/Unsavory Sites of a questionable legal or ethical nature. Sites which promote or distribute products,

information, or devices whose use may be deemed unethical or, in some cases, illegal: Warez, Unlicensed mp3 downloads, Radar detectors, and Street racing. Sample sites: www.thepayback.com and www.strangereports.com.

Egress Filtering Blocking outgoing packets that should not exit a network.

Emergency Response A response to emergencies such as fire, flood, civil commotion, natural disasters, bomb threats, etc., in order to protect lives, limit the damage to property and the impact on MIS operations.

Enciphering The conversion of plaintext or data into unintelligible form by means of a reversible translation that is based on a translation table or algorithm. See also: Encryption.

Encryption The conversion of plaintext or data into unintelligible form by means of a reversible translation that is based on a translation table or algorithm. See also: Enciphering.

End-to-End The inclusion of all requisite components necessary to deliver stated information exchange capability from the information producer's information appliance to the intended user information appliance(s). For SATCOM systems, this implies all components from the user access and display devices, sensors, all associated applications to include the various levels of networking and processing, and all related communications transport mechanisms and associated management services.

Entity Something that exists as independent, distinct or self-contained. For programs, it may be anything that can be described using data, such as an employee, product, or invoice. Data associated with an entity are called attributes. A product's price, weight, quantities in stock, and description all constitute attributes. It is often used in describing distinct business organizations or government agencies.

Environment The aggregate of external circumstance, conditions, and events that affect the development, operation, and maintenance of a system. Environment is often used with qualifiers such as computing environment, application environment, or threat environment, which limit the scope being considered.

Environment of Operation The physical surroundings in which an information system processes, stores, and transmits information.

Evaluation Evaluation is the assessment for conformance with a preestablished metric, criteria, or standard.

Evasion Modifying the format or timing of malicious activity so that its appearance changes but its effect on the target is the same.

Examine A type of assessment method that is characterized by the process of checking, inspecting, reviewing, observing, studying, or analyzing one or more assessment objects to facilitate understanding, achieve clarification, or obtain evidence, the results of which are used to support the determination of security control effectiveness over time.

Executive Agency An executive department specified in 5 U.S.C., Sec. 101; a military department specified in 5 U.S.C., Sec. 102; an independent establishment as defined in 5 U.S.C., Sec. 104(1); and a wholly owned Government corporation fully subject to the provisions of 31 U.S.C., Chapter 91.

Facsimile A document that has been sent, or is about to be sent, via a fax machine.

False Negative An instance in which a security tool intended to detect a particular threat fails to do so.

False Positive An instance in which a security tool incorrectly classifies benign content as malicious.

Federal Agency See: *Executive Agency*.

Federal Information System An information system used or operated by an executive agency, by a contractor of an executive agency, or by another organization on behalf of an executive agency.

File Infector Virus A virus that attaches itself to executable programs, such as word processors, spreadsheet applications, and computer games.

Firewall A collection of components or a system that is placed between two networks and possesses the following properties: 1) all traffic from inside to outside, and vice-versa, must pass through it; 2) only authorized traffic, as defined by the local security policy, is allowed to pass through it; 3) the system itself is immune to penetration.

Firmware Equipment or devices within which computer programming instructions necessary to the performance of the device's discrete functions are electrically embedded in such a manner that they cannot be electrically altered during normal device operations.

Flooding Sending large numbers of messages to a host or network at a high rate. In this publication, it specifically refers to wireless access points.

Flow A particular network communication session occurring between hosts.

Focused Testing A test methodology that assumes some knowledge of the internal structure and implementation detail of the assessment object. Also known as gray box testing.

Friendly Termination The removal of an employee from the organization when there is no reason to believe that the termination is other than mutually acceptable.

Gateway A machine or set of machines that provides relay services between two networks.

General Support System An interconnected set of information resources under the same direct management control which shares common functionality. A system normally includes hardware, software, information, data, applications, communications, and people. A system can be, for example, a local area network (LAN) including smart terminals that support a branch office, an agency-wide backbone, a communications network, a departmental data processing center including its operating system and utilities, a tactical radio network, or a shared information processing service organization (IPSO).

Generic Remote Access Web sites pertaining to the use of, or download of remote access clients.

Global SATCOM Support Center A DoD organization that provides support to joint forces with global operational SATCOM management, maintains situational awareness for current and future SATCOM operations, provides support to anomaly management and resolution, and acts as an interface with the DoD information operations infrastructure.

Gray Box Testing See: *Focused Testing*.

Green Network See: Open Network.

Hack Any software in which a significant portion of the code was originally another program. Many hacked programs simply have the copyright notice removed. Some hacks are done by programmers using code they have previously written that serves as a boilerplate for a set of operations needed in the program they are currently working on. In other cases it simply means a draft. Commonly misused to imply theft of software. See also: Hacker.

Hacker Common nickname for an unauthorized person who breaks into or attempts to break into an MIS by circumventing software security safeguards. Also, commonly called a "cracker." See also: Hack, Intruder.

Hacking Sites discussing and/or promoting unlawful or questionable tools or information revealing the ability to gain access to software or hardware/communications equipment and/or passwords: Password generation, Compiled binaries, Hacking tools and Software piracy (game cracking). Sample sites: www.happyhacker.org, and www.phreak.com.

Hardware Refers to objects that you can actually touch, like disks, disk drives, display screens, keyboards, printers, boards, and chips.

Heuristic Filtering based on heuristic scoring of the content based on multiple criteria.

Hop A communications signal that travels from the ground to the satellite and back to the ground. In some instances the signal needs to be sent to a second satellite, and then back down to the ground; this is called a double hop or two-hop operation.

Host-Based Intrusion Prevention System A program that monitors the characteristics of a single host and the events occurring within the host to identify and stop suspicious activity.

Hostmaster Database A relational database maintained by the Network Engineering Group (CCN-5) that contains information about every device connected to the Laboratory unclassified yellow and green networks.

HTML Anomalies Legitimate companies keep their Web sites up to date and standards based to support the newest browser version support and features and are malicious code free. Malicious sites frequently have HTML code that is not compliant to standards.

Hybrid Security Control A security control that is implemented in an information system in part as a common control and in part as a system-specific control. See: *Common Control* and *System-Specific SecurityControl*.

Identification The process that enables recognition of an entity by a system, generally by the use of unique machine-readable usernames.

IKE Internet Key Exchange.

Incident A violation or imminent threat of violation of computer security policies, acceptable use policies, or standard security practices.

Indication A sign that a malware incident may have occurred or may be occurring.

Individuals An assessment object that includes people applying specifications, mechanisms, or activities.

Industrial Control System An information system used to control industrial processes such as manufacturing, product handling, production, and distribution. Industrial control systems include supervisory control and data acquisition systems used to control geographically dispersed assets, as well as distributed control systems and smaller control systems using programmable logic controllers to control localized processes.

Information An instance of an information type.

Information Owner Official with statutory or operational authority for specified information and responsibility for establishing the controls for its generation, collection, processing, dissemination, and disposal.

Information Resources Information and related resources, such as personnel, equipment, funds, and information technology.

Information Security The protection of information systems against unauthorized access to or modification of information, whether in storage, processing or transit, and against the denial of service to authorized users or the provision of service to unauthorized users, including those measures necessary to detect, document, and counter such threats.

Information Security Officer (ISO) The person responsible to the designated high level manager for ensuring that security is provided for and implemented throughout the life-cycle of an MIS from the beginning of the system concept development phase through its design, development, operations, maintenance, and disposal.

Information Security Program Plan Formal document that provides an overview of the security requirements for an organization-wide information security program and describes the program management controls and common controls in place or planned for meeting those requirements.

Information System (IS) The entire infrastructure, organizations, personnel and components for the collection, processing, storage, transmission, display, dissemination and disposition of information.

Information System Boundary See: *Authorization Boundary*.

Information System Owner (or Program Manager) Official responsible for the overall procurement, development, integration, modification, or operation and maintenance of an information system.

Information Systems Security (INFOSEC) The protection of information assets from unauthorized access to or modification of information, whether in storage, processing, or transit, and against the denial of service to authorized users or the provision of service to unauthorized users, including those measures necessary to detect, document, and counter such threats. INFOSEC reflects the concept of the totality of MIS security. See also: Computer Security.

Information System Security Officer (ISSO) The worker responsible for ensuring that protection measures are installed and operational security is maintained for one or more specific classified information systems and/or networks.

Information System-related Security Risks Information system-related security risks are those risks that arise through the loss of confidentiality, integrity, or availability of information or information systems and consider impacts to the organization (including assets, mission, functions,

image, or reputation), individuals, other organizations, and the Nation. See: *Risk*.

Information Technology Any equipment or interconnected system or subsystem of equipment that is used in the automatic acquisition, storage, manipulation, management, movement, control, display, switching, interchange, transmission, or reception of data or information by the executive agency. For purposes of the preceding sentence, equipment is used by an executive agency if the equipment is used by the executive agency directly or is used by a contractor under a contract with the executive agency which: (i) requires the use of such equipment; or (ii) requires the use, to a significant extent, of such equipment in the performance of a service or the furnishing of a product. The term information technology includes computers, ancillary equipment, software, firmware, and similar procedures, services (including support services), and related resources.

Information Type A specific category of information (privacy, medical, proprietary, financial, investigative, contractor sensitive, security management) defined by an organization or in some instances, by a specific law, Executive Order, directive, policy, or regulation.

Ingress Filtering Blocking incoming packets that should not enter a network.

Inline Sensor A sensor deployed so that the network traffic it is monitoring must pass through it.

Integrated Computing Network (ICN) LANL's primary institutional network.

Integrity A subgoal of computer security which ensures that: 1) data is a proper representation of information; 2) data retains its original level of accuracy; 3) data remains in a sound, unimpaired, or perfect condition; 3) the MIS perform correct processing operations; and 4) the computerized data faithfully represent those in the source documents and have not been exposed to accidental or malicious alteration or destruction. See alsoData Integrity, System Integrity.

Interconnected System An approach in which the network is treated as an interconnection of separately created, managed, and accredited MIS.

Internet A global network connecting millions of computers. As of 1999, the Internet has more than 200 million users worldwide, and that number is growing rapidly.

Interpreted Virus A virus that is composed of source code that can be executed only by a particular application or service.

Interview A type of assessment method that is characterized by the process of conducting discussions with individuals or groups within an organization to facilitate understanding, achieve clarification, or lead to the location of evidence, the results of which are used to support the determination of security control effectiveness over time.

Intranet A network based on TCP/IP protocols (an Internet) belonging to an organization, usually a corporation, accessible only by the organization's members, employees, or others with authorization. An intranet's Web sites look and act just like any other Web sites, but the firewall surrounding an intranet fends off unauthorized access.

Intruder An individual who gains, or attempts to gain, unauthorized access to a computer system or to gain unauthorized privileges on that system. See also: Hacker.

Intrusion Detection Pertaining to techniques, which attempt to detect intrusion into a computer or network by observation of actions, security logs, or audit data. Detection of break-ins or attempts either manually or via software expert systems that operate on logs or other information available on the network.

Intrusion Detection and Prevention The process of monitoring the events occurring in a computer system or network, analyzing them for signs of possible incidents, and attempting to stop detected possible incidents. See also "intrusion prevention".

Intrusion Detection System Load Balancer A device that aggregates and directs network traffic to monitoring systems, such as intrusion detection and prevention sensors.

Intrusion Detection System Software that automates the intrusion detection process.

Intrusion Prevention The process of monitoring the events occurring in a computer system or network, analyzing them for signs of possible incidents, and attempting to stop detected possible incidents. See also "intrusion detection and prevention".

Intrusion Prevention System Software that has all the capabilities of an intrusion detection system and can also attempt to stop possible incidents. Also called an intrusion detection and prevention system.

Invalid Web Pages Sites where a domain may be registered but no content is served or the server is offline.

Ipsec Internet Protocol Security is a framework for a set of security protocols at the network or packet processing layer of network communications. IPsec is ubiquitous amongst firewall, VPNs, and routers.

ISO/AISO The persons responsible to the Office Head or Facility Director for ensuring that security is provided for and implemented throughout the life-cycle of an IT from the beginning of the concept development plan through its design, development, operation, maintenance, and secure disposal.

Issue-Specific Policy Policies developed to focus on areas of current relevance and concern to an office or facility. Both new technologies and the appearance of new threats often require the creation of issue-specific policies (email, Internet usage).

IT Security Measures and controls that protect an IT against denial of and unauthorized (accidental or intentional) disclosure, modification, or destruction of ITs and data. IT security includes consideration of all hardware and/or software functions.

IT Security Policy The set of laws, rules, and practices that regulate how an organization manages, protects, and distributes sensitive information.

IT Systems An assembly of computer hardware, software and/or firmware configured to collect, create, communicate, compute, disseminate, process, store, and/or control data or information.

Jamming The deliberate radiation, re-radiation, or reflection of electromagnetic energy for the purpose of preventing or reducing an enemy's effective use of the electromagnetic spectrum, and with the intent of degrading or neutralizing the enemy's combat capability.

Kerberos Kerberos is a secret-key network authentication system developed by MIT and uses DES for encryption and authentication. Unlike a public-key authentication system, it does not produce digital signatures. Kerberos was designed to authenticate requests for network resources rather than to authenticate authorship of documents. See also: DSS.

Key (digital) A set of code synonymous with key pairs as part of a public key infrastructure. The key pairs include 'private' and 'public' keys. Public keys are generally used for encrypting data and private keys are generally used for signing and decrypting data.

Key Distribution Center A system that is authorized to transmit temporary session keys to principals (authorized users). Each session key is transmitted in encrypted form, using a master key that the key distribution shares with the target principal. See also: DSS, Encryption, Kerberos.

Keystroke Logger A device that monitors and records keyboard usage.

Label The marking of an item of information that reflects its information security classification. An internal label is the marking of an item of information that reflects the classification of that item within the confines of the medium containing the information. An external label is a visible or readable marking on the outside of the medium or its cover that reflects the security classification information resident within that particular medium. See also: Confidentiality.

LAN (Local Area Network) An interconnected system of computers and peripherals. LAN users can share data stored on hard disks in the network and can share printers connected to the network.

Language Content Filtering systems can be used to limit the results of an Internet search to those that are in your native language.

LANL Unclassified Network The LANL unclassified network that consists of two internal networks: the unclassified protected network (Yellow Network) and the open network (Green Network).

LDAP Short for Lightweight Directory Access Protocol, a set of protocols for accessing information directories. LDAP is based on the standards contained within the X.500 standard, but is significantly simpler. And unlike X.500, LDAP supports TCP/IP, which is necessary for any type of Internet access.

Least Privilege The principle that requires each subject be granted the most restrictive set of privileges needed for the performance of authorized tasks. The application of this principle limits the damage that can result from accident, error, or unauthorized use.

Link Layer Layer 2 in the OSI reference model. Responsible for moving data in and out across a physical link.

Local Area Network A short-haul data communications systems that connects IT devices in a building or group of buildings within a few square miles, including (but not limited to) workstations, front end processors, controllers, switches, and gateways.

Macro Virus A virus that attaches itself to application documents, such as word processing files and spreadsheets, and uses the application.s macro programming language to execute and propagate.

Mail header Filtering based solely on the analysis of e-mail headers. Antispam systems try to use this technique as well, but it is not very effective due to the ease of message header forgery.

Mailing List Used to detect mailing list messages and file them in appropriate folders.

Major Application (MA) A computer application that requires special management attention because of its importance to an organization's mission; its high development, operating, and/or maintenance costs; or its significant role in the administration of an organization's programs, finances, property, or other resources.

Malicious Code/Virus Sites that promote, demonstrate and/or carry malicious executable, virus or worm code that intentionally cause harm by modifying or destroying computer systems often without the user's knowledge.

Malware A program that is inserted into a system, usually covertly, with the intent of compromising the confidentiality, integrity, or availability of the victim.s data, applications, or operating system or of otherwise annoying or disrupting the victim.

Management Controls Security methods that focus on the management of the computer security system and the management of risk for a system.

Management Information System (MIS) An MIS is an assembly of computer hardware, software, and/or firmware configured to collect, create, communicate, compute, disseminate, process, store, and/or control data or information. Examples include: information storage and retrieval systems, mainframe computers, minicomputers, personal computers and workstations, office automation systems, automated message processing systems (AMPSs), and those supercomputers and process control computers (embedded computer systems) that perform general purpose computing functions.

Management Network A separate network strictly designed for security software management.

Management Server A centralized device that receives information from sensors or agents and manages them.

Mass Mailing Worm A worm that spreads by identifying e-mail addresses, often by searching an infected system, and then sending copies of itself to those addresses, either using the system.s e-mail client or a self-contained mailer built into the worm itself.

Mechanisms An assessment object that includes specific protection related items (hardware, software, or firmware) employed within or at the boundary of an information system.

Memory Resident A virus that stays in the memory of infected systems for an extended period of time.

Microprocessor A semiconductor central processing unit contained on a single integrated circuit chip.

MIS Owner The official who has the authority to decide on accepting the security safeguards prescribed for an MIS and is responsible for issuing an accreditation statement that records the decision to accept those safeguards. See also: Accreditation Approval (AA), Application Owner, Process Owner.

MIS Security Measures or controls that safeguard or protect an MIS against unauthorized (accidental or intentional) disclosure, modification, destruction of the MIS and data, or denial

of service. MIS security provides an acceptable level of risk for the MIS and the data contained in it. Considerations include: 1) all hardware and/or software functions, characteristics, and/or features; 2) operational procedures, accountability procedures, and access controls at all computer facilities in the MIS; 3) management constraints; 4) physical structures and devices; and 5) personnel and communications controls.

Mission Assurance Category I (MAC I) Systems handling information that is determined to be vital to the operational readiness or mission effectiveness of deployed and contingency forces in terms of both content and timeliness. The consequences of loss of integrity or availability of a MAC I system are unacceptable and could include the immediate and sustained loss of mission effectiveness. MAC I systems require the most stringent protection measures.

Mission Assurance Category II (MAC II) Systems handling information that is important to the support of deployed and contingency forces. The consequences of loss of integrity are unacceptable. Loss of availability is difficult to deal with and can only be tolerated for a short time. The consequences could include delay or degradation in providing important support services or commodities that may seriously impact mission effectiveness or operational readiness. MAC II systems require additional safeguards beyond best practices to ensure assurance.

Mission Assurance Category III (MAC III) Systems handling information that is necessary for the conduct of day-to-day business, but does not materially affect support to deployed or contingency forces in the short-term. The consequences of loss of integrity or availability can be tolerated or overcome without significant impacts on mission effectiveness or operational readiness. The consequences could include the delay or degradation of services or commodities enabling routine activities. MAC III systems require protective measures, techniques, or procedures generally commensurate with commercial best practices.

Mobile Code Software that is transmitted from a remote system to be executed on a local system, typically without the user.s explicit instruction.

Modem An electronic device that allows a microcomputer or a computer terminal to be connected to another computer via a telephone line.

Multipartite Virus A virus that uses multiple infection methods, typically infecting both files and boot sectors.

Multiuser Systems Any system capable of supporting more than one user in a concurrent mode of operation.

National Computer Security Center (NCSC) The government agency part of the National Security Agency (NSA) and that produces technical reference materials relating to a wide variety of computer security areas. It is located at 9800 Savage Rd., Ft. George G. Meade, Maryland.

National Institute of Standards and Technology (NIST) The federal organization that develops and promotes measurement, standards, and technology to enhance productivity, facilitate trade, and improve the quality of life.

National Security Information Information that has been determined pursuant to Executive Order 12958 as amended by Executive Order 13292, or any predecessor order, or by the Atomic Energy Act of 1954, as amended, to require protection against unauthorized disclosure and is marked to indicate its classified status.

National Security System Any information system (including any telecommunications system) used or operated by an agency or by a contractor of an agency, or other organization on behalf of an agency—(i) the function, operation, or use of which involves intelligence activities; involves cryptologic activities related to national security; involves command and control of military forces; involves equipment that is an integral part of a weapon or weapons system; or is critical to the direct fulfillment of military or intelligence missions (excluding a system that is to be used for routine administrative and business applications, for example, payroll, finance, logistics, and personnel management applications); or (ii) is protected at all times by procedures established for information that have been specifically authorized under criteria established by an Executive Order or an Act of Congress to be kept classified in the interest of national defense or foreign policy.

National Telecommunications and Information Systems Security Policy Directs federal agencies, by July 15, 1992, to provide automated Controlled Access Protection (C2 level) for MIS, when all users do not have the same authorization to use the sensitive information.

Need-to-Know Access to information based on clearly identified need to know the information to perform official job duties.

Network A communications medium and all components attached to that medium whose responsibility is the transference of information. Such components may include MISs, packet switches, telecommunications controllers, key distribution centers, and technical control devices.

Network-Based Intrusion Prevention System A program that performs packet sniffing and analyzes network traffic to identify and stop suspicious activity.

Network-Based Intrusion Detection and Prevention System An intrusion detection and prevention system that monitors network traffic for particular network segments or devices and analyzes the network and application protocol activity to identify and stop suspicious activity.

Network Behavior Analysis System An intrusion detection and prevention system that examines network traffic to identify and stop threats that generate unusual traffic flows.

Network Layer Layer 3 in the OSI reference model. Responsible for knowing the logical addresses of nodes, and for selecting routes through the network.

Network Operations Center (NOC) A location that monitors the operation of a network and usually provides efforts to solve connectivity and network problems. The NOC provides management of the terrestrial infrastructure by looking at configuration management and lock-down status/network systems monitoring. Network systems monitoring control sits in the NOC on the terrestrial side and monitors traffic to and from the terrestrial NOC.

Network Security Protection of networks and their services unauthorized modification, destruction, disclosure, and the

provision of assurance that the network performs its critical functions correctly and there are no harmful side-effects.

Network Tap A direct connection between a sensor and the physical network media itself, such as a fiber optic cable.

Network Service Worm A worm that spreads by taking advantage of a vulnerability in a network service associated with an operating system or an application.

NIST National Institute of Standards and Technology in Gaithersburg, Maryland. NIST publishes a wide variety of materials on computer security, including FIPS publications.

Nonrepudiation Method by which the sender is provided with proof of delivery and the recipient is assured of the sender's identity, so that neither can later deny having processed the data.

Nonvolatile Memory Units Devices which continue to retain their contents when power to the unit is turned off (bobble memory, Read-Only Memory/ROM).

Obfuscation Technique A way of constructing a virus to make it more difficult to detect.

Object A passive entity that contains or receives information. Access to an object potentially implies access to the information it contains. Examples of objects are records, blocks, pages, segments, files, directories, directory tree, and programs as well as bits, bytes, words, fields, processors, video displays, keyboards, clocks, printers, network nodes, etc.

Object Reuse The reassignment to some subject of a medium (e.g., page frame, disk sector, or magnetic tape) that contained one or more objects. To be securely reassigned, no residual data from previously contained object(s) can be available to the new subject through standard system mechanisms.

Obscene/Tasteless Sites that contain explicit graphical or text depictions of such things as mutilation, murder, bodily functions, horror, death, rude behavior, executions, violence, and obscenities etc. Sites which contain or deal with medical content *will not* be saved. Sample sites: www.celebritymorgue.com, www.rotten.com, and www.gruesome.com

Offline Pertaining to the operation of a functional unit when not under direct control of a computer. See also: Online.

On-Access Scanning Configuring a security tool to perform real-time scans of each file for malware as the file is downloaded, opened, or executed.

On-Demand Scanning Allowing users to launch security tool scans for malware on a computer as desired.

Online Pertaining to the operation of a functional unit when under the direct control of a computer. See also: Offline.

Open Network A network within the LANL Unclassified Network that supports LANL's public Internet presence and external collaborations. See LANL unclassified network.

Open Systems Interconnection (OSI) Model A standard reference model for communications between two hosts on a network.

Operating System The most important program that runs on a computer. Every general-purpose computer must have an operating system to run other programs. Operating systems perform basic tasks, such as recognizing input from the keyboard, sending output to the display screen, keeping track of files and directories on the disk, and controlling peripheral devices such as disk drives and printers.

Operation Controls Security methods that focus on mechanisms that primarily are implemented and executed by people (as opposed to systems).

Operational Controls The security controls (safeguards or countermeasures) for an information system that are primarily implemented and executed by people (as opposed to systems).

Orange Book Named because of the color of its cover, this is the DoD Trusted Computer System Evaluation Criteria, DoD 5200.28-STD. It provides the information needed to classify computer systems as security levels of A, B, C, or D, defining the degree of trust that may be placed in them. See also: C2, TCSEC.

Organization An entity of any size, complexity, or positioning within an organizational structure (a federal agency or, as appropriate, any of its operational elements).

Organizational Computer Security Representative (OCSR) A LANL person who has oversight responsibilities for one or more single-user, standalone classified or unclassified systems.

Overwrite Procedure A process, which removes or destroys data recorded on a computer storage medium by writing patterns of data over, or on top of, the data stored on the medium.

Overwriting media Method for clearing data from magnetic media. Overwriting uses a program to write (1s, 0s, or a combination) onto the media. Overwriting should not be confused with merely deleting the pointer to a file (which typically happens when a "delete" command is used).

Parity The quality of being either odd or even. The fact that all numbers have parity is commonly used in data communication to ensure the validity of data. This is called parity checking.

Pass Code A one-time-use "authenticator" that is generated by a token card after a user inputs his or her personal identification number (PIN) and that is subsequently used to authenticate a system user to an authentication server or workstation.

Passive Fingerprinting Analyzing packet headers for certain unusual characteristics or combinations of characteristics that are exhibited by particular operating systems or applications.

Passive Sensor A sensor that is deployed so that it monitors a copy of the actual network traffic.

Password A protected word, phrase, or string of symbols used to authenticate a user's identity to a system or network. Guidance note: One-time pass codes are valid only for a single authentication of a user to a system; reusable passwords are valid for repeated authentication of a user to a system.

Payload The portion of a virus that contains the code for the virus.s objective, which may range from the relatively benign (annoying people, stating personal opinions) to the highly malicious (forwarding personal information to others, wiping out systems).

PBX Short for private branch exchange, a private telephone network used within an enterprise. Users of the PBX share a

certain number of outside lines for making telephone calls external to the PBX.

Penetration Testing A test methodology in which assessors, using all available documentation (system design, source code, manuals) and working under specific constraints, attempt to circumvent the security features of an information system.

Peripheral Device Any external device attached to a computer. Examples of peripherals include printers, disk drives, display monitors, keyboards, and mice.

Persistent Cookie A cookie stored on a computer indefinitely so that a Web site can identify the user during subsequent visits.

Personal Identification Number (PIN) A number known only to the owner of the token card and which, once entered, generates a one-time pass-code.

Personnel Security The procedures established to ensure that all personnel who have access to any sensitive information have all required authorities or appropriate security authorizations.

Phishing Deceptive information pharming sites that are used to acquire personal information for fraud or theft. Typically found in hoax e-mail, these sites falsely represent themselves as legitimate Web sites to trick recipients into divulging user account information, credit-card numbers, usernames, passwords, Social Security numbers, etc. Pharming, or crimeware misdirects users to fraudulent sites or proxy servers, typically through DNS hijacking or poisoning.

Phrases Filtering based on detecting phrases in the content text and their proximity to other target phrases.

Physical Layer Layer 1 in the OSI reference model. Responsible for supporting the movement of bits on the physical medium.

Physical Security The application of physical barriers and control procedures as preventative measures or safeguards against threats to resources and information.

Plan of Action and Milestones A document that identifies tasks needing to be accomplished. It details resources required to accomplish the elements of the plan, any milestones in meeting the tasks, and scheduled completion dates for the milestones.

Pornography/Adult Content Sites that portray sexual acts and activity.

Port An interface on a computer to which you can connect a device.

Port Protection Device A device that authorizes access to the port itself, often based on a separate authentication independent of the computer's own access control functions.

Precursor A sign that a malware attack may occur in the future.

Privacy Act of 1974 A US law permitting citizens to examine and make corrections to records the government maintains. It requires that Federal agencies adhere to certain procedures in their record keeping and interagency information transfers. See also: System of Records.

Private Branch Exchange Private Branch eXchange (PBX) is a telephone switch providing speech connections within an organization, while also allowing users access to both public switches and private network facilities outside the organization. The terms PABX, PBX, and PABX are used interchangeably.

Process An organizational assignment of responsibilities for an associated collection of activities that takes one or more kinds of input to accomplish a specified objective that creates an output that is of value.

Process Owner The official who defines the process parameters and its relationship to other Customs processes. The process owner has Accrediting Authority (AA) to decide on accepting the security safeguards prescribed for the MIS process and is responsible for issuing an accreditation statement that records the decision to accept those safeguards. See also: Application Owner.

Promiscuous Mode A configuration setting for a network interface card that causes it to accept all incoming packets that it sees, regardless of their intended destinations.

Protected Distribution System (PDS) A type of protected conduit system used for the protection of certain levels of information. PDS is the highest level of protection and is used in public domain areas for SRD and lower.

Protected Transmission System A cable, wire, conduit, or other carrier system used for the clear text transmission of classified information in certain DOE environments. Protected transmission systems comprise protected distribution systems (PDSs) and classified distributive information networks (CDINs). A wireline or fiber-optic telecommunications system that includes the acoustical, electrical, electromagnetic, and physical safeguards required to permit its use for the transmission of unencrypted classified information.

Proxy A program that receives a request from a client, and then sends a request on the client.s behalf to the desired destination.

Public Law 100-235 Established minimal acceptable standards for the government in computer security and information privacy. See also: Computer Security Act of 1987.

Quarantining Storing files containing malware in isolation for future disinfection or examination.

Radio Frequency (RF) Any frequency within the electromagnetic spectrum normally associated with radio wave propagation. Organizations such as the Federal Communications Commission and International Telecommunication Union have divided the radio frequency spectrum into subdivisions for management purposes.

RADIUS Remote Authentication Dial-in User Service. A long-established de-facto standard whereby user profiles are maintained in a database that remote servers can share and authenticate dial-in users and authorize their request to access a system or service.

Rainbow Series A series of documents published by the National Computer Security Center (NCSC) to discuss in detail the features of the DoD, Trusted Computer System Evaluation Criteria (TCSEC) and provide guidance for meeting each requirement. The name "rainbow" is a nickname because each document has a different color of cover. See also: NCSC.

Read A fundamental operation that results only in the flow of information from an object to a subject.

Real Time Occurring immediately. Real time can refer to events simulated by a computer at the same speed that they would occur in real life.

Reciprocity Mutual agreement among participating organizations to accept each other's security assessments in order to reuse information system resources and/or to accept each other's assessed security posture in order to share information.

Records The recordings (automated and/or manual) of evidence of activities performed or results achieved (forms, reports, test results), which serve as a basis for verifying that the organization and the information system are performing as intended. Also used to refer to units of related data fields (groups of data fields that can be accessed by a program and that contain the complete set of information on particular items).

Recovery The process of restoring an MIS facility and related assets, damaged files, or equipment so as to be useful again after a major emergency which resulted in significant curtailing of normal ADP operations. See also: Disaster Recovery.

Regular Expression Filtering based on rules written as regular expressions.

Remanence The residual information that remains on storage media after erasure. For discussion purposes, it is better to characterize magnetic remanence as the magnetic representation of residual information that remains on magnetic media after the media has been erased. The magnetic flux that remains in a magnetic circuit after an applied magnetomotive force has been removed. See also: Object Reuse.

Remote Access Sites that provide information about or facilitate access to information, programs, online services or computer systems remotely. Sample sites: pcnow.webex.com, and www.remotelyanywhere.com.

Remote Administration Tool A program installed on a system that allows remote attackers to gain access to the system as needed.

Residual Risk The risk of operating a classified information system that remains after the application of mitigating factors. Such mitigating factors include, but are not limited to minimizing initial risk by selecting a system known to have fewer vulnerabilities, reducing vulnerabilities by implementing countermeasures, reducing consequence by limiting the amounts and kinds of information on the system, and using classification and compartmentalization to lessen the threat by limiting the adversaries' knowledge of the system.

Risk The probability that a particular threat will exploit a particular vulnerability of the system.

Risk Analysis The process of identifying security risks, determining their magnitude, and identifying areas needing safeguards. An analysis of an organization's information resources, its existing controls, and its remaining organizational and MIS vulnerabilities. It combines the loss potential for each resource or combination of resources with an estimated rate of occurrence to establish a potential level of damage in dollars or other assets. See also: Risk Assessment, Risk Management.

Risk Assessment Process of analyzing threats to and vulnerabilities of an MIS to determine the risks (potential for losses), and using the analysis as a basis for identifying appropriate and cost-effective measures. See also: Risk Analysis, Risk Management. Risk analysis is a part of risk management, which is used to minimize risk by specifying security measures commensurate with the relative values of the resources to be protected, the vulnerabilities of those resources, and the identified threats against them. The method should be applied iteratively during the system life-cycle. When applied during the implementation phase or to an operational system, it can verify the effectiveness of existing safeguards and identify areas in which additional measures are needed to achieve the desired level of security. There are numerous risk analysis methodologies and some automated tools available to support them.

Risk Executive (Function) An individual or group within an organization that helps to ensure that: (i) security risk-related considerations for individual information systems, to include the authorization decisions, are viewed from an organization wide perspective with regard to the overall strategic goals and objectives of the organization in carrying out its missions and business functions; and (ii) managing information system-related security risks is consistent across the organization, reflects organizational risk tolerance, and is considered along with other organizational risks affecting mission/business success.

Risk Management The total process of identifying, measuring, controlling, and eliminating or minimizing uncertain events that may affect system resources. Risk management encompasses the entire system life-cycles and has a direct impact on system certification. It may include risk analysis, cost/benefit analysis, safeguard selection, security test and evaluation, safeguard implementation, and system review. See also: Risk Analysis, Risk Assessment.

Router An interconnection device that is similar to a bridge but serves packets or frames containing certain protocols. Routers link LANs at the network layer.

ROM Read Only Memory. See also: Nonvolatile Memory Units.

Rootkit A collection of files that is installed on a system to alter the standard functionality of the system in a malicious and stealthy way.

Route Hijacking A routing-based denial of service attack involves attackers manipulating routing table entries to deny service to legitimate systems or networks.

RSA A public-key cryptosystem for both encryption and authentication based on exponentiation in modular arithmetic. The algorithm was invented in 1977 by Rivest, Shamir, and Adelman and is generally accepted as practical or secure for public-key encryption. See also: Capstone, Clipper, DES, RSA, Skipjack.

Rules of Behavior Rules established and implemented concerning use of, security in, and acceptable level of risk for the system. Rules will clearly delineate responsibilities and expected behavior of all individuals with access to the system. Rules should cover such matters as work at home, dial-in access, connection to the Internet, use of copyrighted

works, unofficial use of Federal Government equipment, the assignment and limitation of system privileges, and individual accountability.

Safeguards Countermeasures, specifications, or controls, consisting of actions taken to decrease the organizations existing degree of vulnerability to a given threat probability, that the threat will occur.

Satellites Craft positioned hundreds to thousands of miles in space to efficiently relay a wide variety of broadcast and two-way communications across great distances.

Satellite Communications (SATCOM) A satellite communications system is comprised of three segments: Space Segment, Control Segment, and Terminal (Ground) Segment.

Satellite Control Stations Monitor satellite health and command the mission operations and maintenance functions of satellites and system components. Satellite control stations are typically divided into the SOC and the NOC.

Satellite Operations Center (SOC) One or more facilities that supports space segment operations by providing pre-launch planning, launch and early orbit support, and satellite control functions. SOC personnel perform satellite command and control during launch, on-orbit test, and deployment, and assist in major anomaly resolution.

Security Incident An MIS security incident is any event and/or condition that has the potential to impact the security and/or accreditation of an MIS and may result from intentional or unintentional actions. See also: Security Violation.

Security Authorization See: *Authorization*.

Security Categorization The process of determining the security category for information or an information system. Security categorization methodologies are described in CNSS Instruction 1253 for national security systems and in FIPS 199 for other than national security systems.

Security Control Assessment The testing and/or evaluation of the management, operational, and technical security controls in an information system to determine the extent to which the controls are implemented correctly, operating as intended, and producing the desired outcome with respect to meeting the security requirements for the system.

Security Control Assessor The individual, group, or organization responsible for conducting a security control assessment.

Security Control Baseline One of the sets of minimum security controls defined for federal information systems in NIST Special Publication 800-53 and CNSS Instruction 1253.

Security Control Enhancements Statements of security capability to: (i) build in additional, but related, functionality to a basic control; and/or (ii) increase the strength of a basic control.

Security Control Inheritance A situation in which an information system or application receives protection from security controls (or portions of security controls) that are developed, implemented, assessed, authorized, and monitored by entities other than those responsible for the system or application; entities either internal or external to the organization where the system or application resides. See: *Common Control*.

Security Controls The management, operational, and technical controls (safeguards or countermeasures) prescribed for an information system to protect the confidentiality, integrity, and availability of the system and its information.

Security Impact Analysis The analysis conducted by an organizational official to determine the extent to which changes to the information system have affected the security state of the system.

Security Objective Confidentiality, integrity, or availability.

Security Plan Document that details the security controls established and planned for a particular system.

Security Policy The set of laws, rules, directives, and practices that regulate how an organization manages, protects, and distributes controlled information.

Security Requirements Types and levels of protection necessary for equipment, data, information, applications, and facilities to meet security policies.

Security Safeguards (Countermeasures) The protective measures and controls that are prescribed to meet the security requirements specified for a system. Those safeguards may include, but are not necessarily limited to: hardware and software security features; operating procedures; accountability procedures; access and distribution controls; management constraints; personnel security; and physical structures, areas, and devices. Also called safeguards or security controls.

Security Specifications A detailed description of the security safeguards required to protect a system.

Security Violation An event, which may result in disclosure of sensitive information to, unauthorized individuals, or that results in unauthorized modification or destruction of system data, loss of computer system processing capability, or loss or theft of any computer system resources. See also: Security Incident.

Senior Agency Information Security Officer Official responsible for carrying out the Chief Information Officer responsibilities under FISMA and serving as the Chief Information Officer's primary liaison to the agency's authorizing officials, information system owners, and information system security officers. [Note: Organizations subordinate to federal agencies may use the term *Senior Information Security Officer* or *Chief Information SecurityOfficer* to denote individuals filling positions with similar responsibilities to Senior Agency Information Security Officers.]

Senior Information Security Officer See: *Senior Agency Information Security Officer*.

Sensitive Data Any information, the loss, misuse, modification of, or unauthorized access to, could affect the national interest or the conduct of federal programs, or the privacy to which individuals are entitled under Section 552a of Title 5, U.S. Code, but has not been specifically authorized under criteria established by an Executive order or an act of Congress to be kept classified in the interest of national defense or foreign policy.

Sensitive Unclassified Information Information for which disclosure, loss, misuse, alteration, or destruction could adversely affect national security or other federal government interests. Guidance Note: National security interests are those unclassified matters that relate to the national

defense or to United States (US) foreign relations. Other government interests are those related to, but not limited to, a wide range of government or government-derived economic, human, financial, industrial, agricultural, technological, and law-enforcement information, and to the privacy or confidentiality of personal or commercial proprietary information provided to the U.S. government by its citizens. Examples are Unclassified Controlled Nuclear Information (UCNI), Official Use Only (OUO) information, Naval Nuclear Propulsion Information (NNPI), Export Controlled Information (ECI), In Confidence information, Privacy Act information (such as personal/medical information), proprietary information, for example, from a cooperative research and development agreement (CRADA), State Department Limited Official Use (LOU) information, and Department of Defense For Official Use Only (FOUO) information.

Sensitivity Level Sensitivity level is the highest classification level and classification category of information to be processed on an information system.

Sensor An intrusion detection and prevention system component that monitors and analyzes network activity and may also perform prevention actions.

Separation of Duties The dissemination of tasks and associated privileges for a specific computing process among multiple users to prevent fraud and errors.

Server The control computer on a local area network that controls software access to workstations, printers, and other parts of the network.

Session Cookie A temporary cookie that is valid only for a single Web site session.

Shim A layer of host-based intrusion detection and prevention code placed between existing layers of code on a host that intercepts data and analyzes it.

Signature A set of characteristics of known malware instances that can be used to identify known malware and some new variants of known malware.

Signature-Based Detection The process of comparing signatures against observed events to identify possible incidents.

Site Usually a single physical location, but it may be one or more MIS that are the responsibility of the DSO. The system may be a standalone MIS, a remote site linked to a network, or workstations interconnected via a local area network (LAN).

Skipjack A classified NSA designed encryption algorithm contained in the Clipper Chip. It is substantially stronger than DES and intended to provide a federally mandated encryption process, which would enable law enforcement agencies to monitor and wiretap private communications. See also: Capstone, Clipper, DES, RSA, Skipjack.

Smart Card A credit-card – sized device with embedded microelectronics circuitry for storing information about an individual. This is not a key or token, as used in the remote access authentication process.

SNMP Simple Networking Management Protocol.

Software Computer instructions or data. Anything that can be stored electronically is software.

Software Copyright The right of the copyright owner to prohibit copying and/or issue permission for a customer to employ a particular computer program.

Space Segment There are two parts to the space segment: ground elements and satellite(s), each comprised of platform (the basic structure and subsystems of the satellite) and payload. The payload provides space-based capabilities to the users and distinguishes one type of satellite from another.

SPAM To crash a program by overrunning a fixed-site buffer with excessively large input data. Also, to cause a person or newsgroup to be flooded with irrelevant or inappropriate messages.

Spanning Port A switch port that can see all network traffic going through the switch.

Specification An assessment object that includes document-based artifacts (policies, procedures, plans, system security requirements, functional specifications, and architectural designs) associated with an information system.

Spyware Sites that promote, offer or secretively install software to monitor user behavior, track personal information, record keystrokes, and/or change user computer configuration without the user's knowledge and consent malicious or advertising purposes. Includes sites with software that can connect to "phone home" for transferring user information.

Spyware Detection and Removal Utility A program that monitors a computer to identify spyware and prevent or contain spyware incidents.

Standard Security Procedures Step-by-step security instructions tailored to users and operators of MIS that process sensitive information.

Standalone System A single-user MIS not connected to any other systems.

Stateful Protocol Analysis The process of comparing predetermined profiles of generally accepted definitions of benign protocol activity for each protocol state against observed events to identify deviations.

Stealth Mode Operating an intrusion detection and prevention sensor without IP addresses assigned to its monitoring network interfaces.

Subsystem A major subdivision or component of an information system consisting of information, information technology, and personnel that performs one or more specific functions.

Supplementation (Assessment Procedures) The process of adding assessment procedures or assessment details to assessment procedures in order to adequately meet the organization's risk management needs.

Supplementation (Security Controls) The process of adding security controls or control enhancements to a security control baseline from NIST Special Publication 800-53 or CNSS Instruction 1253 in order to adequately meet the organization's risk management needs.

Symmetric Encryption See: Conventional Encryption.

System An organized hierarchy of components (hardware, software, data, personnel, and communications, for example) having a specified purpose and performance requirements.

System Administrator The individual responsible for the installation and maintenance of an information system, providing effective information system utilization, required security parameters, and implementation of established requirements.

System Availability The state that exists when required automated informations can be performed within an acceptable time period even under adverse circumstances.

System Failure An event or condition that results in a system failing to perform its required function.

System Integrity The attribute of a system relating to the successful and correct operation of computing resources. See also: Integrity.

System of Records A group of any records under the control of the Department from which information is retrieved by the name of an individual, or by some other identifying number, symbol, or other identifying particular assigned to an individual. See also: Privacy Act of 1974.

System Owner The person, team, group, or division that has been assigned and accepted responsibility for Laboratory computer assets.

System Recovery Actions necessary to restore a system's operational and computational capabilities, and its security support structure, after a system failure or penetration.

System Security Plan Formal document that provides an overview of the security requirements for an information system and describes the security controls in place or planned for meeting those requirements.

System-Specific Security Control A security control for an information system that has not been designated as a common control or the portion of a hybrid control that is to be implemented within an information system.

System User An individual who can receive information from, input information to, or modify information on a LANL information system without an independent review. Guidance Note: This term is equivalent to computer information system user, or computer user, found in other Laboratory documentation. System users may be both LANL workers and collaborators. For desktop systems, a single individual may be a system user and system owner.

Tailoring The process by which a security control baseline is modified based on: (i) the application of scooping guidance; (ii) the specification of compensating security controls, if needed; and (iii) the specification of organization-defined parameters in the security controls via explicit assignment and selection statements.

Tailoring (Assessment Procedures) The process by which assessment procedures defined in Special Publication 800-53A are adjusted, or scoped, to match the characteristics of the information system under assessment, providing organizations with the flexibility needed to meet specific organizational requirements and to avoid overly-constrained assessment approaches.

Tailored Security Control Baseline A set of security controls resulting from the application of tailoring guidance to the security control baseline. See *Tailoring*.

TCP/IP Transmission Control Protocol/Internet Protocol. The Internet Protocol is based on this suite of protocols.

TCSEC Trusted Computer System Evaluation Criteria (TCSEC). DoD 5200.28-STD, National Institute of Standards and Technology (NIST), Gaithersburg, Maryland, 1985. Establishes uniform security requirements, administrative controls, and technical measures to protect sensitive information processed by DoD computer systems. It provides a standard for security features in commercial products and gives a metric for evaluating the degree of trust that can be placed in computer systems for the securing of sensitive information. See also: C2, Orange Book.

Technical Controls Security methods consisting of hardware and software controls used to provide automated protection to the system or applications. Technical controls operate within the technical system and applications.

Technical Security Policy Specific protection conditions and/or protection philosophy that express the boundaries and responsibilities of the IT product in supporting the information protection policy control objectives and countering expected threats.

Telecommunications Any transmission, emission, or reception of signals, writing, images, sound or other data by cable, telephone lines, radio, visual or any electromagnetic system.

Terminal (Ground) Segment This segment comprises the actual equipment that receives and transmits signals to the satellite. Terminals can vary from a hand-held or man-pack terminal to a large fixed installation.

Terrestrial Data Links Network connections that tie together the control stations, ground stations, and the rest of the terrestrial telecommunications infrastructure.

Terrorist/Militant/Extremist Sites that contain information regarding militias, anti-government groups, terrorism, anarchy, etc.: Anti-government/Anti-establishment and bomb-making/usage (Should also be saved in criminal skills). Sample sites: www.michiganmilitia.com, www.militiaof-montana.com, and www.ncmilitia.org.

Test A type of assessment method that is characterized by the process of exercising one or more assessment objects under specified conditions to compare actual with expected behavior, the results of which are used to support the determination of security control effectiveness over time.

Test Condition A statement defining a constraint that must be satisfied by the program under test.

Test Data The set of specific objects and variables that must be used to demonstrate that a program produces a set of given outcomes. See also: Disaster Recovery, Test Program.

Test Plan A document or a section of a document which describes the test conditions, data, and coverage of a particular test or group of tests. See also: Disaster Recovery, Test Condition, Test Data, Test Procedure (Script).

Test Procedure (Script) A set of steps necessary to carry out one or a group of tests. These include steps for test environment initialization, test execution, and result analysis. The test procedures are carried out by test operators.

Test Program A program which implements the test conditions when initialized with the test data and which collects the results produced by the program being tested. See also: Disaster Recovery, Test Condition, Test Data, Test Procedure (Script).

The Computer Security Plans for General Support Systems (GSS) and Major Applications (MA) Plans that detail the specific protection requirements for major applications and general support systems.

The Cyber Security Handbook A Web-site handbook that details the Cyber Security requirements required by system

users, system administrators, and SRLMs who access electronic information.

Threat An event, process, activity (act), substance, or quality of being perpetuated by one or more threat agents, which, when realized, has an adverse effect on organization assets, resulting in losses attributed to: direct loss, related direct loss, delays or denials, disclosure of sensitive information, modification of programs or databases and intangible (good will, reputation, etc.).

Threat Agent Any person or thing, which acts, or has the power to act, to cause, carry, transmit, or support a threat. See also: Threat.

Threat Assessment Process of formally evaluating the degree of threat to an information system or enterprise and describing the nature of the threat.

Threat Source The intent and method targeted at the intentional exploitation of a vulnerability or a situation and method that may accidentally trigger a vulnerability. Synonymous with threat agent.

Threshold A value that sets the limit between normal and abnormal behavior.

Token Card A device used in conjunction with a unique PIN to generate a one-time pass code (for example, CRYPTOCard® or SecureID)®).

Tracking Cookie A cookie placed on a user.s computer to track the user.s activity on different Web sites, creating a detailed profile of the user.s behavior.

Transmission Security (TRANSEC) Component of COMSEC resulting from the TRANSEC application of measures designed to protect transmissions from interception and exploitation by means other than cryptanalysis.

Transport Layer Layer 4 of the OSI reference model. Ensures the reliable delivery of messages and provides error-checking mechanisms.

Trapdoor A secret undocumented entry point into a computer program, used to grant access without normal methods of access authentication. See also: Malicious Code.

Triangulation Identifying the physical location of a detected threat against a wireless network by estimating the threat's approximate distance from multiple wireless sensors by the strength of the threat's signal received by each sensor, then calculating the physical location at which the threat would be the estimated distance from each sensor.

Trigger A condition that causes a virus payload to be executed, usually occurring through user interaction (opening a file, running a program, clicking on an e-mail file attachment).

Trojan Horse A computer program with an apparently or actually useful function that contains additional (hidden) functions that surreptitiously exploit the legitimate authorizations of the invoking process to the detriment of security. See also: Malicious Code. Threat Agent.

Trusted Computer Base (TCB) The totality of protection mechanisms within a computer system, including hardware, firmware, and software, the combination of which is responsible for enforcing a security policy. A TCB consists of one or more components that together enforce a security policy over a product or system. See also: C2, Orange Book, TCSEC.

Trusted Computing System A computer and operating system that employs sufficient hardware and software integrity measures to allow its use for simultaneously processing a range of sensitive information and can be verified to implement a given security policy.

Tuning Altering the configuration of an intrusion detection and prevention system to improve its detection accuracy.

Unclassified Cyber Security Program Plan A plan that provides a single source of unclassified computer security program information, and specifies the minimum protections and controls and references the detailed source material that pertains to the program.

Unclassified Information Systems Security Site Manager The manager responsible for the LANL Unclassified Information Systems Security Program.

Unclassified Protected Network A network within the LANL unclassified network that is designed to protect the resident systems from unauthorized access and is separated from the Internet by a firewall that controls external access to the network. See also: LANL Unclassified Network.

Unfriendly Termination The removal of an employee under involuntary or adverse conditions. This may include termination for cause, RIF, involuntary transfer, resignation for "personality conflicts," and situations with pending grievances.

Uplink The portion of a communications link used to transmit signals from an Earth-based terminal (on land, ship, or aircraft) to a satellite.

UPS (Uninterruptible Power Supply) A system of electrical components to provide a buffer between utility power, or other power source, and a load that requires uninterrupted, precise power. This often includes a trickle-charge battery system which permits a continued supply of electrical power during brief interruption (blackouts, brownouts, surges, electrical noise, etc.) of normal power sources.

User Any person who is granted access privileges to a given IT.

User Interface The part of an application that the user works with. User interfaces can be text-driven, such as DOS, or graphical, such as Windows.

Verification The process of comparing two levels of system specifications for proper correspondence.

Very Small Aperture Terminal (VSAT) Refers to small Earth station employing a satellite antenna with a diameter or cross-section dimension in the general range of 1.2 to 2.4 meters. VSAT terminals are used in networks that primarily support point-to-multipoint communications as part of large private networks, particularly in large retail networks to support transactions such as inventory management and credit-card authorizations.

Virus Code imbedded within a program that causes a copy of itself to be inserted in one or more other programs. In addition to propagation, the virus usually performs some unwanted function. Note that a program need not perform malicious actions to be a virus; it need only infect other programs. See also: Malicious Code.

VSAN Virtual SAN.

Vulnerability A weakness, or finding that is non-compliant, non-adherent to a requirement, a specification or a standard,

or unprotected area of an otherwise secure system, which leaves the system open to potential attack or other problem.

WAN (Wide Area Network) A network of LANs, which provides communication, services over a geographic area larger than served by a LAN.

Web Browser Plug-In A mechanism for displaying or executing certain types of content through a Web browser.

Web Bug A tiny graphic on a Web site that is referenced within the Hypertext Markup Language (HTML) content of a Web page or e-mail to collect information about the user viewing the HTML content.

Whitelist A list of discrete entities, such as hosts or applications, that are known to be benign.

Wireless Intrusion Detection and Prevention System An intrusion detection and prevention system that monitors wireless network traffic and analyzes its wireless networking protocols to identify and stop suspicious activity involving the protocols themselves.

World Wide Web An association of independent information databases accessible via the Internet. Often called the Web, WWW, or W.

Worm A computer program that can replicate itself and send copies from computer to computer across network connections. Upon arrival, the worm may be activated to replicate and propagate again. In addition to propagation, the worm usually performs some unwanted function. See also: Malicious Code.

Worms Worms are a type of virus that consume memory and network bandwidth, and can ultimately cause a computer to stop responding. Worms can permit an attacker to access computers remotely and require no user action to spread.

Write A fundamental operation that results only in the flow of information from a subject to an object.

WWW See: World Wide Web.

Yellow Network See LANL Unclassified Network.

Zombie A program that is installed on a system to cause it to attack other systems.

Configuring Authentication Service on Microsoft Windows 7

John R. Vacca

This appendix describes the configuration of Windows 7 authentication service features that are relevant to IT professionals. The authentication service features included with Windows 7 extend to a strong set of platform-based authentication features to help provide better security, manageability, and user experience.

1. CONFIGURING WINDOWS 7 AUTHENTICATION (WEB SERVER (IIS 7))

Use Windows authentication when you want clients to authenticate using the NT LAN Manager (NTLM) or Kerberos protocols. The default authentication configuration for IIS 7 enables Anonymous authentication only [1].

Windows authentication, which includes both NTLM and Kerberos v5 or higher authentication, is best suited for an intranet environment for the following reasons:

- Client computers and Web servers are in the same domain.
- Administrators can make sure that every client browser is Internet Explorer 2.0 or later versions.
- HTTP proxy connections, which are not supported by NTLM, are not required.
- Kerberos v5 or higher requires a connection to Active Directory, which is not feasible in an Internet environment [1].

Important

Windows Authentication is not supported by Home or Starter editions of Windows Vista® and Windows® 7. To see which IIS features are supported on your operating system, see one of the following:

- If you are using Windows Vista® or Windows Server® 2008, see Available Role Services in IIS 7.0 (http://technet.microsoft.com/en-us/library/cc753473(WS.10).aspx).
- If you are using Windows® 7 or Windows Server® 2008 R2, see Available Web Server (IIS) Role Services in IIS 7.5 (http://technet.microsoft.com/en-us/library/cc753473.aspx) [1].

Windows authentication is not appropriate for use in an Internet environment, because that environment does not require or encrypt user credentials. The default setting for Windows authentication is Negotiate. This setting means that the client can select the appropriate security support provider. To force NTLM authentication, you must change the value of the **<Provider>** element under the **<windowsAuthentication>** element in the ApplicationHost.config file [1].

Prerequisites

For information about the levels at which you can perform this procedure, and the modules, handlers, and permissions that are required to perform this procedure, see Authentication Feature Requirements (IIS 7) (http://technet.microsoft.com/en-us/library/cc755253(v=ws.10).aspx) [1].

Exceptions to Feature Requirements

None

Modules

WindowsAuthenticationModule: To configure Windows authentication, you can perform this procedure by using the user interface (UI), by running Appcmd.exe commands in a command-line window, by editing configuration files directly, or by writing Windows Management Instrumentation (WMI) scripts [1].

User Interface (UI)

To use the UI, open IIS Manager and navigate to the level you want to manage. For information about opening IIS

Manager, see Open IIS Manager (IIS 7) (http://technet.microsoft.com/en-us/library/cc770472(v=ws.10).aspx). For information about navigating to locations in the UI, see Navigation in IIS Manager (IIS 7) (http://technet.microsoft.com/en-us/library/cc732920(v=ws.10).aspx):

1. In **Features View**, double-click **Authentication**.
2. On the **Authentication** page, select **Windows Authentication**.
3. In the **Actions** pane, click **Enable** to use Windows authentication [1].

Note

*Optionally, you can disable Kernel-mode authentication by clicking **Advanced Settings**. As a best practice, you should not disable this setting if you use Kerberos authentication and a custom identity on the application pool* [1].

Command Line

To enable or disable Windows authentication, use the following syntax [1]:

appcmd set config /section:windowsAuthentication /enabled:true | false

By default, IIS sets the **enabled** attribute to false, which disables Windows authentication. If you set the attribute to true, you enable Windows authentication. For example, to enable Windows Authentication, type the following at the command prompt, and then press ENTER [1]:

appcmd set config /section:windowsAuthentication /enabled:true

Optionally, you can force Windows authentication to use NTLM, using the following syntax [1]:

appcmd set config /section:windowsAuthentication /-providers.[value = 'Negotiate']

For more information about Appcmd.exe, see Appcmd.exe (IIS 7) (http://msdn.microsoft.com/en-us/library/aa347559.aspx).

Configuration

The procedure in this topic affects the following configuration elements [1]:

<windowsAuthentication>

For more information about IIS 7 configuration, see IIS 7.0: IIS Settings Schema (http://msdn.microsoft.com/en-us/library/aa347559.aspx) on MSDN [1].

WMI

Use the following WMI classes, methods, or properties to perform this procedure [1]:

WindowsAuthenticationSection class

For more information about WMI and IIS, see Windows Management Instrumentation (WMI) in IIS 7 (http://technet.microsoft.com/en-us/library/cc771707(v=ws.10).aspx). For more information about the classes, methods, or properties associated with this procedure, see the IIS WMI Provider Reference (http://msdn.microsoft.com/en-us/library/Aa347459) on the MSDN site [1].

2. CONFIGURING AUTHENTICATION IN IIS 7

Authentication helps you confirm the identity of clients who request access to your sites and applications. IIS 7 supports Anonymous and Integrated Windows authentication by default [2].

IIS 7 supports both *challenge-based* and *login redirection-based* authentication methods. A challenge-based authentication method, for example, Integrated Windows authentication, requires a client to respond correctly to a server-initiated challenge. A login redirection-based authentication method, for example, Forms authentication, relies on redirection to a login page to determine the identity of the user. You cannot use both a challenge-based authentication method and a login redirection-based authentication method at the same time [2].

IIS 7 also supports client certificate authentication, which requires that Secure Sockets Layer (SSL) be configured for the site. For more information about client certificates, see Configuring Server Certificates in IIS 7 http://technet.microsoft.com/en-us/library/cc732230(v=ws.10).aspx) [2].

Prerequisites

For information about the levels at which you can perform these procedures, and the modules, handlers, and permissions that are required to perform these procedures, see Authentication Feature Requirements (IIS 7) (http://technet.microsoft.com/en-us/library/cc755253(v=ws.10).aspx) [2].

Procedures

This task includes the following procedures [2]:

- Configure the Anonymous Authentication Identity (IIS 7) [http://technet.microsoft.com/en-us/library/cc770966(v=ws.10).aspx]
- Configure ASP.NET Impersonation Authentication (IIS 7) [http://technet.microsoft.com/en-us/library/cc730708(v=ws.10).aspx]
- Configure Basic Authentication (IIS 7) [http://technet.microsoft.com/en-us/library/cc772009(v=ws.10).aspx]

- Configure Client Certificate Mapping Authentication (IIS 7) [http://technet.microsoft.com/en-us/library/cc732996(v=ws.10).aspx]
- Configure Digest Authentication (IIS 7) [http://technet.microsoft.com/en-us/library/cc754104(v=ws.10).aspx]
- Configuring Forms Authentication (IIS 7) [http://technet.microsoft.com/en-us/library/cc753252(v=ws.10).aspx]
- Configure Windows Authentication (IIS 7) [http://technet.microsoft.com/en-us/library/cc754628(v=ws.10).aspx]
- Configure Extended Protection in IIS 7.5 [http://technet.microsoft.com/en-us/library/ee909472(v=ws.10).aspx]

Security Management and Resiliency

John R. Vacca

The United States needs to strengthen the computer security management and resilience component of its homeland security strategy to mitigate the effect of successful terrorist attacks and other disasters. As a nation, the U.S. must be able to withstand a blow and then bounce back. That's resilience![1]

The U.S. can mitigate risk but cannot guarantee that another attack will not occur, nor can it prevent natural and accidental disasters. It requires this country to admit that some disasters cannot be avoided. It also requires the U.S. to acknowledge that, faced with disaster, most citizens, businesses, and other institutions will take action to rescue themselves and others.[1]

According to U.S. government analysts, 90% of the country's critical infrastructure is privately owned and operated. However, it isn't the job of the government to do the on-the-ground work of security management and resiliency.[1]

The private sector can provide the means and the execution. On the other hand, it should also be the champion and the facilitator of security management and resiliency chain; balancing the interests of stakeholders; setting broad objectives and strategies; and providing oversight.[1]

However, the creativity and ingenuity of the American people must also be taken into consideration, including the businesses they create. This also includes how government can prepare its citizens for a disaster or an emergency by giving them the necessary security management tools.[1]

The government's first goal is to provide timely and accurate security management information during a crisis. Government must also leverage technology to help inform citizens that danger is near. The Department of Homeland Security (DHS) has created the Ready Business program, which gives small-to-medium-size businesses guidance on which security management and resiliency tools and resources are available to them to ensure business continuity.[1]

The government's second goal is to provide order, so citizens can focus on disaster response, rather than protecting themselves from social chaos. While local and state forces can maintain order during a disaster; just in case they cannot, DHS is studying specialized law enforcement deployment teams (LEDTs). These teams from neighboring jurisdictions would assist local and state forces when they are taxed to the breaking point. LEDTs could help provide an organized system that would allow state and local law enforcement to assist each other to quickly resume normal police services, to an area hit by a terrorist attack or natural disaster (something Louisiana and New Orleans police did not have after Hurricane Katrina struck).[1]

Finally, the government can increase infrastructure security management and resilience after an attack or disaster. Nevertheless, this can be done through the dispersal of key functions across multiple service providers, flexible supply chains, and related systems.[1]

Business should build in such flexibility as well. Flexibility, is cheaper than redundancy, and it is also a smart business decision because it makes companies more competitive.[1]

A company that builds in the ability to respond to supply disruption is automatically building in the ability to respond to demand fluctuations and winning market share. For the past 16 years, AT&T has invested in mobile central offices: 500 trailers that hold everything the company needs to keep their network up and running. On 9/11, AT&T dispatched these trailers to New York because the terrorist attack had knocked out a company transport hub in the sixth subbasement of the World Trade Center's South Tower. Within 48 hours, the trailers were operational and accepting call traffic.[1]

Finally, the United States has been too focused on prevention to the detriment of security management and resilience. After 9/11, the Bush administration focused solely on preventing the next attack, as opposed to how best to recover should an incident occur. That, of course, is not the best approach.[1]

List of Top Information and Network Security Implementation and Deployment Companies

Aaditya Corporation (www.aadityacorp.com/): Network Security Consultants offering specialization in network security policy definition.

Advent Information Management Ltd (www.adventim.co.uk/): Knowledge-based consultancy offering information management advice, training and consultancy.

AMPEG Security Lighthouse (www.security-lighthouse.com/): Produce information security management software which provides a national and international perspective on your company's security status.

Atsec (www.atsec.com/01/index.php): Offers a range of services based on the Common Criteria standard, ISO 15408.

BindView Policy Compliance (www.symantec.com/business/solutions/index.jsp?ptid=tab2&ctid=tab2_2): Provides organizations with advanced tools to proactively build and measure security best practices across the enterprise.

CF6 Luxembourg S.A. (www.cf6.lu/): Security policies are the formalization of security needs in order to define security measures for implementation. CF6 Luxembourg proposes to help companies to develop and implement security policies.

Citicus ONE-security risk management (www.citicus.com/index.asp): Citicus provides tools for information risk management to ensure that compliance with security policy can be monitored and enhanced.

Computer Policy Guide (www.computerpolicy.com/): A commercial manual with sample policies. Topics include: Email; Internet Usage; Personal Computer Usage; Information Security; and Document Retention.

CoSoSys SRL (www.fortedownloads.com/CoSoSys-SRL-Surf-it-Easy/): Provides software to protect PC endpoints and networks.

Delta Risk LLC (www.delta-risk.net/): Provides information on a range of policy related services, including risk assessment, awareness and training.

DynamicPolicy – Efficient Policy Management (www.zequel.com/): DynamicPolicy is an Intranet application that enables companies to automatically create, manage and disseminate their corporate policies and procedures, particularly those related with Information Security.

FoolProof Software – Desktop Security for windows and MAC OS-education and libraries (www.foolproofsoftware.com/assets/cm.js): FoolProof Security provides complete protection for both Windows® and Macintosh® operating systems and desktops by preventing unwanted or malicious changes from being made to the system.

Information Management Technologies (www.imt.com.sa/files/index.asp): Saudi Arabia. BS7799 Audit; Forensic Services and Training; Data Recovery Laboratory; Managed Security Service Provider; Security Control Frameworks.

Information Security and IT Security Austria (www.eclipse-security.at/): Austrian Information Security and IT-Security Company offering Consulting Services, Information Security Awareness Training in German and English language, and M.M.O.S.S Software (Massive Multiuser Online Sensitiving Software).

Information Shield, Inc. (www.informationshield.com/): A global provider of prepackaged security policies and customizable implementation guidance.

IT Security Essentials Guide (www.ovitztaylor-gates.com/TheITSecurityEssentialsGuide.html): Management resources for enterprise projects, offering how-to workbooks, project plans and planning guides, tools, templates and checklists.

Layton Technology Inc. (www.laytontechnology.com/): Offers a range of Windows based audit, monitoring and access control software solutions.

Megaprime (www.megaprime.com.au/): Offers ISO/IEC 17799 compliant information security policy and management systems, security architectures, secure applications and networks.

Pirean Limited Homepage (www.pirean.com/): Providing enterprise systems, risk management and information security services, applications and education with

a focus on security management and international standards (BS7799/ISO17799).

Policy Manager — Cisco Systems (www.cisco.com/en/US/products/sw/netmgtsw/ps996/ps5663/index.html): Cisco Secure Policy Manager is a scalable, powerful security policy management system for Cisco firewalls and Virtual Private Network (VPN) gateways. Assistance is also provided with the development and auditing of security policy.

Prolateral Consulting (www.prolateral.com/): Consultancy for ISO17799 BS7799, Information Security Management.

Prolify (www.prolify.com/): Prolify delivers Dynamic Process Management (DPM) solutions for IT Governance, enabling enterprises to achieve higher levels of control, efficiency and compliance.

PSS Systems (www.pss-systems.com/): Document policy management and enforcement for electronic documents. Enterprise software to protect, track and ensure the destruction of highly mobile, distributed assets.

Ruskwig Security Portal (www.ruskwig.com/): Provides security policies, an encryption package, security policy templates, Internet and email usage policies.

Secoda Risk Management (www.secoda.com/): RuleSafe from Secoda enables the people in your organization to achieve real awareness of policies. Expert content and compliance tracking help organizations implement security (BS7799), privacy and regulatory requirements.

Security Policies & Baseline Standards: Effective Implementation (www.security.kirion.net/securitypolicy/): Discussion of topic with security policies and baseline standards information.

- Singular Security (www.singularsecurity.com/): A firm specializing in delivering security configuration management services designed to mitigate both computing and company-wide policy compliance requirements.
- Spry Control LLC (www.sprycontrol.com/): Spry Control provides Information Technology Audit Services as a part of corporate oversight or external audit that address information security, data privacy and technology risks.
- VantagePoint Security (www.vantagepointsecurity.com/): Professional services firm specializing in security policy, assessments, risk mitigation, and managed services.
- Vision training and consultancy: Dedicated to onsite consultancy and training in the following elements: BS7799 and ISO90012000.
- Xbasics, LLC: Offers information security and FISMA-related software for government, industry and consulting organizations.

1. LIST OF SAN IMPLEMENTATION AND DEPLOYMENT COMPANIES

There are many different SAN implementation and deployment companies that offer products and services, from very large companies to smaller, lesser-known ones. A list of some of the more well-known companies is offered here:

Bull: www.bull.com/index.php
Dell: www.dell.com
EMC: www.emc.com
Fujitsu: www.fujitsu.com/global/services/computing/storage/system/
HP: welcome.hp.com/country/us/en/prodserv/storage.html
Hitachi Data Systems: www.hds.com/products/storage-networking/
IBM: www-03.ibm.com/systems/storage/
NetApp: www.netapp.com/us/
NEC: www.nec.co.jp/necstorage/global/index.shtml
3PAR: www.3par.com/index.html
Sun: www.sun.com/storagetek/networking.jsp
Xiotech: www.xiotech.com/

2. SAN SECURITY IMPLEMENTATION AND DEPLOYMENT COMPANIES:[1]

McData SANtegrity Security Suite Software (www.mcdata.com/products/network/security/santegrity.html): SANtegrity Security Suite enhances business continuity by reducing the impact of human influences on your networked data. This robust suite of software applications provides unsurpassed storage area network (SAN) protection. SANtegrity lets you build secure storage networks by providing end-to-end security features for McD fabrics. Using SANtegrity software, you can apply layers of security to individual storage network ports, switches and entire fabrics through: Multi-level Access Control, Advanced Zoning Security, Secure Management zones, SANtegrity Features and Functions.

Brocade Secure Fabric OS (www.brocade.com/products/silkworm/silkworm_12000/fabric_os_datasheet.jsp): A Comprehensive SAN Security Solution. As a greater number of organizations implement larger Storage Area Networks (SANs), they are facing new challenges in regard to data and system security. Especially as organizations interconnect SANs over longer distances through existing networks, they have an even greater need to effectively manage their security and policy requirements. To help these organizations improve security, Brocade has developed Secure Fabric OS™, a comprehensive

1. SAN Security, www.sansecurity.com/san-security-vendors.shtml

security solution for Brocade-based SAN fabrics that provides policy-based security protection for more predictable change management, assured configuration integrity, and reduced risk of downtime. Secure Fabric OS protects the network by using the strongest, enterprise-class security methods available, including digital certificates and digital signatures, multiple levels of password protection, strong password encryption, and Public Key Infrastructure (PKI)-based authentication, and 128-bit encryption of the switch's private key used for digital signatures.

Hifn 4300 HIPP III Storage Security Processor (www.hifn.com/products/4300.html): The Hifn™ HIPP III 4300 Storage Security Processor is the first security processor designed for the specific requirements of IP Storage applications. The 4300 offers a complete IPsec data path solution optimized for IP Storage based systems, combining inbound and outbound policy processing, SA lookup, SA context handling, and packet formatting – all within a single chip. Hifn's 4300 delivers industry-leading cryptographic functionality, supporting the DES/3DES-CBC, AES-CBC, AES-CTR, MD5, SHA-1 and AES-XCBC-MAC algorithms. Hifn also provides complete software support, including an optional onboard iSCSI-compliant IPsec software stack, offering an embedded HTML manager application.

HP StorageWorks Secure Fabric OS (javascript:var%20handle=window.open ('h18006.www1.hp.com/products/storage/software/sansecurity/): HP Secure Fabric OS solutions include a comprehensive SAN infrastructure security software tool and value added services for 1 Gb and 2 Gb SAN Switches environments. With its flexible design, the Security feature enables organizations to customize SAN fabric security in order to meet specific policy requirements. In addition, Security Fabric OS works with security practices already deployed in many SAN environments such as Advanced Zoning. HP Services also provide a portfolio of services ranging from the broad SAN Design and Architecture that can provide a complete multisite security design, to a single site Security Installation & Startup service that shows you how to configure your Secure Fabric OS environment using the most used industry tested aspects of security. HP Secure Fabric OS is a complete solution for securing SAN infrastructures.

Decru Dataform Security Appliances (www.decru.com/): Decru DataFort™ is a reliable, multigigabit-speed encryption appliance that integrates transparently into NAS, SAN, DAS and tape backup environments. By locking down stored data with strong encryption, and routing all access through secure hardware, DataFort radically simplifies the security model for networked storage. DataFort appliances combine secure access controls, authentication, storage encryption, and secure logging to provide unprecedented protection for sensitive stored data. Because DataFort protects data at rest and in flight with strong encryption, even organizations that outsource IT management can be sure their data assets are secure. In short, DataFort offers a powerful and cost-effective solution to address a broad range of external, internal, and physical threats to sensitive data.

Kasten Chase Assurency (www.kastenchase.com/): Assurency™ SecureData provides comprehensive security for data storage, including SAN, NAS and DAS. Utilizing authentication, access control and strong industry-standard encryption, SecureData protects valuable information stored on online, near-line, and backup storage media. These safeguards extend to stored data both within the datacenter and at offsite data storage facilities. Assurency SecureData protects valuable data assets, such as email, financial and health care information, customer and personnel records and intellectual property. For government agencies, Assurency SecureData protects intelligence and national defense data, law enforcement information, and confidential citizen records. Helps build trusted brands that earn customer loyalty and retention.

List of Security Products

John Vacca

1. SECURITY SOFTWARE

Activeworx (www.crosstecsoftware.com/security/index.html): Activeworx provides organizations with comprehensive, real time expert security information analysis combined with strong correlation intelligence, flexible and robust reporting capabilities, and tight integration with our best of breed logging solution.

Ad-Aware 2008 Definition File (www.download.com/Ad-Aware-2008-Definition-File/3000-8022_4-10706164.html): Updates your Ad-Aware 2007 definition file to the latest release.

Ad-Aware 2008 (www.download.com/Ad-Aware-2008/3000-8022_4-10045910.html): Protects your personal home computer from malware attacks.

ArcSight (www.arcsight.com/product_overview.htm): The ArcSight SIEM Platform is an integrated set of products for collecting, analyzing, and managing enterprise event information. These products can be purchased and deployed separately or together, depending on organization size and needs.

Ashampoo Fire Wall (www.download.com/Ashampoo-FireWall/3000-10435_4-10575187.html): Sets up an effective firewall and prevents unauthorized online activity.

Avast Virus Cleaner Tool (www.download.com/Avast-Virus-Cleaner-Tool/3000-2239_4-10223809.html): Removes selected viruses and worms from your computer.

AVG Anti-Virus (www.download.com/AVG-Anti-Virus/3000-2239_4-10385707.html): Protects your computer from viruses and malicious programs.

AVG Internet Security (www.download.com/AVG-Internet-Security/3000-2239_4-10710160.html): Protects your PC from harmful Internet threats.

Avira AntiVir Personal-Free Antivirus (www.download.com/Avira-AntiVir-Personal-Free-Antivirus/3000-2239_4-10322935.html): Detects and eliminates viruses, get free protection for home users.

Avira Premium Security Suite (www.download.com/Avira-Premium-Security-Suite/3000-2239_4-10683930.html): Protects your workstation from viruses and online threats.

CCleaner (www.download.com/CCleaner/3000-2144_4-10315544.html): Cleans up junk files and invalid Registry entries.

Comodo Firewall Pro (www.download.com/Comodo-Firewall-Pro/3000-10435_4-10460704.html): Protects your PC from harmful threats.

ESET NOD32 Antivirus (www.download.com/ESET-NOD32-Antivirus/3000-2239_4-10185608.html): Protects your system against viruses.

Folder Lock (www.download.com/Folder-Lock/3000-2092_4-10063343.html): Password-protects, locks, hides or encrypts files, folders, drives and portable disks in seconds.

Hotspot Shield (www.download.com/Hotspot-Shield/3000-2092_4-10594721.html): Maintains your anonymity and protects your privacy when accessing free Wi-Fi hotspots.

Intelinet Spyware Remover (www.download.com/Intelinet-Spyware-Remover/3000-8022_4-10888927.html): Removes and blocks all types of spyware and PC errors on your computer.

Kaspersky Anti-Virus (www.download.com/Kaspersky-Anti-Virus/3000-2239_4-10259842.html): Monitors and detects viruses and protects your PC from viruses, malware, and Trojan attacks.

Kaspersky Anti-Virus Definition Complete Update (www.download.com/Kaspersky-Anti-Virus-Definition-Complete-Update/3000-2239_4-10059428.html): Updates your Kaspersky Anti-Virus with the latest overall set of virus definitions.

Kaspersky Internet Security (www.download.com/Kaspersky-Internet-Security/3000-2239_4-10012072.html): Detects and eliminates viruses and Trojan horses, even new and unknown ones.

KeyScrambler Personal (www.download.com/KeyScrambler-Personal/3000-2144_4-10571274.html): Encrypts keystrokes to protect your username and password from keyloggers.

Malwarebytes' Anti-Malware (www.download.com/Malwarebytes-Anti-Malware/3000-8022_4-10804572.html): Detects and removes malware from your computer.

McAfee VirusScan Plus (www.download.com/McAfee-VirusScan-Plus/3000-2239_4-10581368.html): Removes spyware or virus threats and prevents malicious applications from invading your PC.

Norton 360 (www.download.com/Norton-360/3000-2239_4-10651162.html): Surround yourself with protection from viruses, spyware, fraudulent Web sites, and phishing scams.

Norton AntiVirus 2009 (www.download.com/Norton-AntiVirus-2009/3000-2239_4-10592477.html): Protects yourself from all forms of online viruses.

Norton AntiVirus 2009 Definitions Update (www.download.com/Norton-AntiVirus-2009-Definitions-Update/3000-2239_4-10737487.html): Updates virus definitions for your Norton AntiVirus and Internet Security 2008 products.

Norton Internet Security (www.download.com/Norton-Internet-Security/3000-8022_4-10592551.html): Prevents viruses, spyware, and phishing attacks to enjoy secure Web connection.

Online Armor Personal Firewall (www.download.com/Online-Armor-Personal-Firewall/3000-10435_4-10426782.html): Protects your system from parasites, viruses, and identity theft while surfing the Web.

ParentalControl Bar (www.download.com/ParentalControl-Bar/3000-2162_4-10539075.html): Prevents your children from accessing adult-oriented Web sites.

Password Dragon (www.download.com/Password-Dragon/3000-2092_4-10844722.html): Manages your passwords and keeps them in a safe place.

PeerGuardian (www.download.com/PeerGuardian/3000-2144_4-10438288.html): Protect yourself on P2P networks by blocking IPs.

RSA Envision (www.rsa.com/node.aspx?id=3170): The RSA en Vision platform provides the power to gather and use log data to understand your security, compliance, or operational status in real time or over any period of time.

Secunia Personal Software Inspector (www.download.com/Secunia-Personal-Software-Inspector/3000-2162_4-10717855.html): Scans your installed programs and categorizes them by their security-update status.

Spybot-Search & Destroy (www.download.com/Spybot-Search-amp-Destroy/3000-8022_4-10122137.html): Searches your hard disk and Registry for threats to your security and privacy.

SpywareBlaster (www.download.com/SpywareBlaster/3000-8022_4-10196637.html): Prevents spyware from being installed on your computer.

Spyware Doctor (www.download.com/Spyware-Doctor/3000-8022_4-10293212.html): Remove spyware, adware, Trojan horses, and key loggers with this popular and fast utility.

Syslog NG (www.balabit.com/network-security/syslog-ng/): The syslog-ng application is a flexible and highly scalable system logging application that is ideal for creating centralized and trusted logging solutions.

Trend Micro AntiVirus plus AntiSpyware (www.download.com/Trend-Micro-AntiVirus-plus-AntiSpyware/3000-2239_4-10440657.html): Detects and removes adware and spyware from your home computer.

Trend Micro HijackThis (www.download.com/Trend-Micro-HijackThis/3000-8022_4-10227353.html): Scans the Registry and hard drive for spyware.

Zone Alarm Firewall (Windows 2000/XP): (www.download.com/ZoneAlarm-Firewall-Windows-2000-XP-/3000-10435_4-10039884.html): Protects your Internet connection from hackers and other security breaches.

ZoneAlarm Internet Security Suite (www.download.com/ZoneAlarm-Internet-Security-Suite/3000-8022_4-10291278.html): Equips your system to deal with Web-based security threats including hackers, viruses, and worms.

List of Security Standards

BITS Financial Services Roundtable (www.bits.org/FISAP/index.php): Security assessment questionnaire and review process based on ISO/IEC 27002 (access requires free registration). Also information on the overlaps between ISO/IEC 27002, PCI-DSS 1.1 and COBIT.

Common Criteria (www.commoncriteriaportal.org/thecc.html): Provides the Common Criteria for Information Technology Security Evaluation, also published as ISO/IEC 15408.

ISO 27001 Certificates (iso27001certificates.com/): List of organizations certified against ISO/IEC 27001 or equivalent national standards, maintained by the ISMS International User Group based on inputs from all the certification bodies.

ISO 27000 Directory (www.27000.org/): Information covering the ISO/IEC 27000 series of standards, including updates and consultants directory.

ISO 27001 Security (www.iso27001security.com/): Information about the ISO/IEC 27000-series information security standards and other related standards, with discussion forum and FAQ.

ISO 27000 Toolkit (www.17799-toolkit.com/): Package containing the ISO/IEC 27001 and 27002 standards plus supporting materials such as policies and a glossary.

ISO/IEC 27002 Explained (www.berr.gov.uk/whatwedo/sectors/infosec/infosecadvice/legislationpolicystandards/securitystandards/isoiec27002/page33370.html): Information on ISO/IEC 27001 and 27002 from BERR, the UK government department for Business Enterprise and Regulatory Reform (formerly the DTI, the Department of Trade and Industry).

ISO/IEC 27001 Frequently Asked Questions (www.atsec.com/01/index.php?id=06-0101-01): FAQ covers the basics of ISO/IEC 27001, the ISO/IEC standard Specification for an Information Security Management System.

NIST Special Publication 800-53 (csrc.nist.gov/publications/nistpubs/800-53-Rev2/sp800-53-rev2-final.pdf): Recommended Security Controls for Federal Information Systems has a similar scope to ISO/IEC 27002 and cross-references the standard. [PDF]

Overview of Information Security Standards (www.infosec.gov.hk/english/technical/files/overview.pdf): Report by the Government of the Hong Kong Special Administrative Region outlines the ISO/IEC 27000-series

Federal Information Processing Standards (FIPS)

Number	Date	Title
FIPS 201–2	Jul 9, 2012	DRAFT Personal Identity Verification (PIV) of Federal Employees and Contractors (REVISED DRAFT) draft_nist-fips-201-2_revised.pdf

standards plus related standards, regulations etc. including PCI-DSS, COBIT, ITIL/ISO 20000, FISMA, SOX and HIPAA. [PDF]

Praxiom Research Group Ltd. (praxiom.com/#ISO%20IEC%2027001%20LIBRARY): Plain English descriptions of ISO/IEC 27001, 27002 and other standards, including a list of the controls.

The Security Practitioner (security.practitioner.com/intro-duction/): The ISO 27001 Perspective: An Introduction to Information Security is a guide to ISO/IEC 27001 and 27002 in the form of an HTML help file.

Veridion (www.veridion.net/): ISO/IEC 27001 and 27002 training courses including Lead Auditor and Lead Implementer, plus other information security, risk management and business continuity courses on BS 25999, CISSP, CISA, CISM, MEHARI and OCTAVE.

List of Miscellaneous Security Resources

The following is a list of miscellaneous security resources:

- Conferences
- Consumer Information
- Directories
- Help and Tutorials
- Mailing Lists
- News and Media
- Organizations
- Products and Tools
- Research
- Content Filtering Links
- Other Logging Resources

1. CONFERENCES

Airscanner: Wireless Security Boot Camp (www.airscanner.com/wireless/): Wireless security training conference held in Dallas, Texas, USA.

AusCERT (conference.auscert.org.au/conf2009/): International conference focusing on IT security. Held near Brisbane, Australia.

DallasCon (www.dallascon.com/): Provides information and wireless security training with hands-on boot camps throughout the U.S. as well as annual conference in Dallas, Texas.

FIRST Conference (www.first.org/conference/) : Annual international conference focused on handling computer security incidents. Location varies.

Infosecurity (www.infosec.co.uk/page.cfm/Link=18/t=m/trackLogID=2317009_A50169F58F): Global series of annual IT Security exhibitions.

International Computer Security Audit and Control Symposium (www.cosac.net/): This annual conference held in Ireland is for IT security professionals.

ITsecurityEvents (www.itsecurityevents.com/): Calendar listing IT security events worldwide.

Network and Distributed System Security Symposium (www.isoc.org/includes/javascript.js): Annual event aimed at fostering information exchange among research scientists and practitioners of network and distributed system security services. Held in San Diego, California.

NISC (www.nisc.org.uk/): Information security conference in Scotland. Details of agenda, guest speakers and online booking form.

The Training Co. (www.thetrainingco.com/): Techno-Security conference organizers and computer security training providers. Conference details, including registration and pricing.

VP4S-06: Video Processing for Security (www.computer-vision.org/4security/): Conference focused on processing video data from security devices.

2. CONSUMER INFORMATION

AnonIC (www.anonic.org/): A free resource for those in need of Internet privacy. The aim of this site is to educate Internet users how to protect their privacy at little or no cost.

Business.gov: Information and Computer Security Guide (www.business.gov/guides/privacy/): Provides links to plain language government resources that help businesses secure their information systems, protecting mission-critical data.

Computer Security information for the rest of us. (www.secure-computing.info/): Computer Security information in plain language. Learn how to protect your computer from viruses, spyware and spam.

Consumer Guide to Internet Safety, Privacy and Security (nclnet.org/essentials/): Offers tips and advice for maintaining online privacy and security, and how to keep children safe online.

EFS File Encryption Tutorial (www.iopus.com/guides/efs.htm): Learn how to use the free Microsoft Encrypting File System (EFS) to protect your data and how to back up your private key to enable data recovery.

GRC Security Now (www.grc.com/securitynow.htm): Provides access to weekly podcasts and whitepapers on topics like Windows Vista, computer security, virus advisories, and other interesting hacking topics.

Home Network Security (www.cert.org/tech_tips/home_networks.html): Gives home users an overview of the security risks and countermeasures associated with Internet connectivity, especially in the context of "always-on" or broadband access services such as cable modems and DSL.

Internet Security Guide (www.internetsecurityguide.com/): Features articles on business and home user Internet security including SSL certificates and network vulnerability scanning.

Online Security Tips for Consumers of Financial Services (www.bits.org/ci_consumer.html): Advice for conducting secure online transactions.

Outlook Express Security Tutorial (www.iopus.com/guides/oe-backup.htm): Learn how to back up your Outlook Express (OE) email, investigate the Windows Registry and transfer your email account and rules settings to another PC.

An Overview of email and Internet Monitoring in the Workplace (www.fmew.com/archive/monitoring/): Compliance with the law that governs employer monitoring of employee Internet usage and personal email in the workplace.

Privacy Initiatives (www.ftc.gov/privacy/): Government Site that is run by the Federal Trade Commission. Information about how the government can help protect kids and the general public. It has lots of information about official policies.

Protect Your Privacy and email on the Internet (www.taciroglu.com/p/): Guide to protecting privacy and personal information. Includes information on protecting passwords, email software, IP numbers, encryption, firewalls, anti-virus software, and related resources.

Spyware watch (www.spyware.co.uk/): Spyware information and tools.

Staysafe.org (staysafe.org/): Educational site intended to help consumers understand both the positive aspects of the Internet as well as how to manage a variety of safety and security issues that exist online.

Susi (www.besafeonline.org/English/safer_use_of_services_on_the_internet.htm): Information and advice to parents and teachers, about risks on the Internet and how to behave.

Wired Safety (www.wiredsafety.org/): Offers advice about things that can go wrong online, including con artists, identity thieves, predators, stalkers, criminal hackers, fraud, cyber-romance gone wrong and privacy problems. Includes contact form.

3. DIRECTORIES

E-Evidence Information Center (www.e-evidence.info/): Directory of material relating to all aspects of digital forensics and electronic evidence.

Itzalist (www.itzalist.com/com/computer-security/index.html): Computer resources offering antivirus software, current virus news, antivirus patches, online protection, security software and other information about computer security.

The Laughing Bit (www.tlb.ch/): Collection of links to information on Windows NT and Checkpoint Firewall-1 security.

Safe World (soft.safeworld.info/): Directory of links to downloadable security software. Brief descriptions for each.

SecureRoot (www.secureroot.com/): Hacking and security related links. Also offers discussion forums.

4. HELP AND TUTORIALS

How to find security holes (www.canonical.org/%7Ekragen/security-holes.html): Short primer originally written for the Linux Security Audit project.

Ronald L. Rivest's Cryptography and Security (people.csail.mit.edu/rivest/crypto-security.html): Provides links to cryptography and security sites.

SANS Institute – The Internet Guide To Popular Resources On Computer Security (www.sans.org/410.php): Combination FAQ and library providing answers to common information requests about computer security.

5. MAILING LISTS

Alert Security Mailing List (www.w3.easynet.co.uk/unitel/services/alert.html): Monthly security tips and alert mailing list. Pay subscription service provides information, tips and developments to protect your Internet computer security.

Computer Forensics Training Mailing List (www.infosecinstitute.com/courses/computer_forensics_training.html): Computer forensics and incident response mailing list.

FreeBSD Resources (www.freebsd.org/doc/en_US.ISO8859-l/books/handbook/eresources.html): Mailing lists pertaining to FreeBSD. freebsd-security and freebsd-security-notifications are sources of official FreeBSD specific notifications.

InfoSec News (www.infosecnews.org/): Privately-run medium traffic list that caters to distribution of information security news articles.

ISO17799 & ISO27001 News (www.molemag.net/): News, background and updates on these international security standards.

IWS INFOCON Mailing List (www.iwar.org.uk/general/mailinglist.htm): The INFOCON mailing list is devoted to the discussion of cyber threats and all aspects of information operations, including offensive and defensive information warfare, information assurance, psychological operations, electronic warfare.

Risks Digest (catless.ncl.ac.uk/Risks): Forum on risks to the public in computers and related systems.

SCADA Security List (www.infosecinstitute.com/courses/scada_security_training.html): Mailing list concerning DCS and SCADA Security.

SecuriTeam Mailing Lists (www.securiteam.com/mailinglist.html): Location of various security mailing lists pertaining to exploits, hacking tools, and others.

Security Clipper (www.securityclipper.com/alarm-systems.php): Mailing list aggregator offering a selection of security lists to monitor.

6. NEWS AND MEDIA

Security Focus (www.securityfocus.com/): News and editorials on security related topics, along with a database of security knowledge.

Computer Security News-Topix (www.topix.com/tech/computer-security): News on computer security continually updated from thousands of sources around the net.

Computer Security Now (www.computersecuritynow.com/): Computer security news and information now for the less security oriented members of the community.

Enterprise Security Today (www.enterprise-security-today.com/fullpage/fullpage.xhtml?dest=%2F): Computer security news for the I.T. Professional.

Hagai Bar-El-Information Security Consulting (www.hbarel.com/news.html): Links to recent information security news articles from a variety of sources.

Help Net Security (www.net-security.org/): Help Net Security is a security portal offering various information on security issues-news, vulnerabilities, press releases, software, viruses and a popular weekly newsletter.

Investigative Research into Infrastructure Assurance Group (news.ists.dartmouth.edu/): News digests arranged by subject with links to full articles. Subjects include cybercrime, regulation, consumer issues and technology.

O'Reilly Security Center (oreilly.com/pub/topic/security): O'Reilly is a leader in technical and computer book documentation for Security.

SecureLab (www.securelab.com/): Computer and network security software, information, and news.

SecuriTeam (www.securiteam.com/): Group dedicated to bringing you the latest news and utilities in computer security. Latest exploits with a focus on both Windows and Unix.

Security Geeks (securitygeeks.shmoo.com/): Identity and information security news summaries with discussion and links to external sources.

Security Tracker (securitytracker.com/): Information on the latest security vulnerabilities, free Security Tracker Alerts, and customized vulnerability notification services.

Xatrix Security (www.xatrix.org/): Security news portal with articles, a search engine and books.

7. ORGANIZATIONS

Association for Automatic Identification and Mobility (www.aimglobal.org/): Global trade association for the Automatic Identification and Data Capture (AIDC) industry, representing manufacturers, consultants, system integrators, and users involved in technologies that include barcode, RFID, card technologies, biometrics, RFDC, and their associated industries.

Association for Information Security (www.iseca.org/): Non-profit organization aiming to increase public awareness and facilitate collaboration among information security professionals worldwide. Offers security documents repository, training, news and joining information. Headquarters in Sofia, Bulgaria.

First (www.first.org/): Forum of Incident Response and Security Teams.

Information Systems Audit and Control Association (www.isaca.org/): Worldwide association of IS professionals dedicated to the audit, control, and security of information systems. Offer CISA qualification and COBIT standards.

IntoIT (www.intosaiitaudit.org/): The journal of the INTOSAI EDP Audit Committee. Its main focuses are on information systems auditing, IT performance auditing, and IT support for auditing.

North Texas Chapter ISSA (issa-northtexas.org/): The Dallas and Fort Worth chapter of the Information Systems Security Association (ISSA).

RCMP Technical Security Branch (www.rcmp-grc.gc.ca/tsb/): Canadian organization dedicated to providing federal government clients with a full range of professional physical and information technology security services and police forces with high technology forensic services.

The Shmoo Group (www.shmoo.com/): Privacy, crypto, and security tools and resources with daily news updates.

Switch-CERT (www.switch.ch/cert/): Swiss CERT-Team from the Swiss research network (Switch).

8. PRODUCTS AND TOOLS

AlphaShield (www.alphashield.com/): Hardware product used with your DSL or cable modem which disconnects the "always on" connection when the Internet is not in use, and prevents unauthorized access to your computer.

Bangkok Systems & Software (www.bangkoksystem.com/): System and software security. Offices in Thailand and India.

Beijing Rising International Software Co., Ltd (www.rising-global.com/): Chinese supplier of antivirus, firewall, content management and other network security software and products.

Beyond If Solutions (www.beyondifsolutions.com/): Supplier of encryption and biometric devices, mobile device management software and remote network access.

BootLocker Security Software (www.bootlocker.com/): BootLocker secures your computer by asking for a password on startup. Features include multiple user support, screensaver activation, system tray support, and logging.

Calyx Suite (www.calyxsuite.com/): Offer token or biometric based authentication, with associated firewall, encryption and single sign-on software. Technical documentation, reseller listings and trial downloads. Located in France.

CipherLinx (www.cipherlinx.com/): Secure remote control technology using Skipjack encryption.

ControlGuard (www.controlguard.com/): Provides access control solutions for portable devices and removable media storage. [May not work in all browsers.]

CT Holdings, Inc. (www.ct-holdings.com/): Develops, markets and supports security and administration software products for both computer networks and desktop personal computers. (Nasdaq: CITN).

Cyber-Defense (enclaveforensics.com/): Links to free software tools for security analysis, content monitoring and content filtering.

Data Circle (www.datacircle.com/app/homepage.asp): Products include Datapass, Dataware, and Dataguide.

Digital Pathways Services Ltd UK (www.digpath.co.uk/): Providing specialized security products for encryption, risk assessment, intrusion detection, VPNs, and intrusion detection.

Diversinet Corp. (www.dvnet.com/): Develops digital certificate products based on public-key infrastructures and technologies required for corporate networks, intranets and electronic commerce on the Internet for a variety of security authentication applications. (Nasdaq: DVNT).

DLA Security Systems, Inc. (www.dlaco.com/): Key control software, key records management software, master keying software.

DSH (www.dshi.com/): Commercial and GSA reseller for Arbor Networks, Entercept, Netforensics and Solsoft.

eLearning Corner (www.elearningcorner.com/): Flash based, scorm-compatible online computer security awareness courses to improve corporate IT security by modifying employee behaviors.

Enclave Data Solutions (enclavedatasolutions.com/): Reseller of MailMarshal, WebMarshal, Jatheon email archival, Akonix IM and other security products.

eye4you (www.eye4you.com.au/): Software to monitor and restrict PC usage, enforce acceptable use policies, teach classes and prevent students changing vital system files.

Faronics (www.faronics.com/): Develops and markets end-point non-restrictive, configuration management and whitelist based software security solutions.

Forensic Computers (www.forensic-computers.com/index.php): Provides specialized computer systems, security and forensic hardware and software.

GFI Software Ltd (www.gfi.com/languard/): Offers network security software including intrusion detection, security scanner, anti virus for Exchange and anti virus for ISA server.

Global Protective Management.com (www.secureassess.com/): Providing Global Security Solutions. GPM has created a unique suite of PC-based security software applications called SecureAssess. The SecureAssess product line takes full advantage of current mobile technologies to provide clients with tools to effectively address their security vulnerabilities.

GuardianEdge Technologies, Inc. (www.guardianedge.com/): Encryption for hard disks and removable storage, authentication, device control and smart phone protection, within a shared infrastructure giving consolidated administration.

Hotfix Reporter (www.maximized.com/freeware/hotfixreporter/): Works with Microsoft Network Security Hotfix Checker (HfNetChk) to scan for security holes, and outputs Web pages complete with links to the Microsoft articles and security patches.

IPLocks Inc. (www.iplocks.com/): Database security, monitoring, auditing reporting for governance and compliance.

iSecurityShop (www.isecurityshop.com/): Offers hardware and software network security products including firewalls, cryptographic software, antivirus, and intrusion detection systems.

Juzt-Innovations Ltd. (www.juzt-innovations.ie/): PC data backup and recovery card, 3DES encryption utility and smart card access control system.

KAATAN Software (www.kaatansoftware.com/): Developer of security software including encryption of office documents and SQLserver database auditing.

Kilross Network Protection Ltd. (www.kilross.com/): Irish reseller of IT security products from eSoft, SecPoint, SafeNet and others.

Lexias Incorporated (www.lexias.com/): Provides next generation solutions in data security and high availability data storage.

Lexura Solutions Inc. (www.lexurasolutions.com/index.htm): Software for encryption, intruder alerting and cookie management.

Locum Software Services Limited (www.locumsoftware.co.uk/): Security solutions for Unisys MCP/AS systems.

Lumigent Technologies (www.lumigent.com/): Enterprise data auditing solutions that help organizations mitigate the inherent risks associated with data use and regulatory compliance.

Marshal (www.marshal.com/): Supplier of email and Web security software.

n-Crypt (www.n-crypt.co.uk/): Develops integrated security software products for the IT industry.

NetSAW: Take a look at your network (www.proquesys.com/). This is a new enterprise class network security product currently being developed by ProQueSys that provides both security experts as well as hobbyists with an understanding of the communications on their computer networks.

Networking Technologies Inc. (www.nwtechusa.com/): Distributor of email security, antivirus, Web filtering and archival products.

New Media Security (www.newmediasecurity.com/): Provides solutions to protect data on mobile computers, laptops, PDAs, tablets and in emails and on CDs.

NoticeBored (www.noticebored.com/html/site_map.html): Information security awareness materials for staff, managers and IT professionals covering a fresh topic every month.

Noweco (www.noweco.com/smhe.htm): Proteus is a software tool designed to audit information security management systems according to ISO17799 standards.

Oakley Networks Inc. (www.oakleynetworks.com/): Security systems capable of monitoring 'leakage' of intellectual property through diverse routes such as Web, email, USB and printouts.

Pacom Systems (www.pacomsystems.com/): Provider of integrated and networked security solutions for single- and multisite organizations.

Paktronix Systems: Network Security (www.paktronix.com/): Design, supply, and implement secure networks. Provide secure border Firewall systems for connecting networks to the Internet or each other. Offer Network Address Translation (NAT), Virtual Private Networking (VPN), with IPSec, and custom port translation capabilities.

PC Lockdown (www.pclockdown.com.au/): Software that allows the remote lockdown of networked workstations. Product features, company information, FAQ and contact details.

Porcupine.org (www.porcupine.org/): Site providing several pieces of software for protecting computers against Internet intruders.

Powertech (www.powertech.com/powertech/index.asp): Security software for the IBM AS/400 and iSeries including intrusion detection, user access control, encryption and auditing.

Protocom Development Systems (www.actividentity.com/): Specializes in developing network security software for all needs with credential management, strong authentication, console security and password reset tools.

Sandstorm Enterprises (www.sandstorm.net/): Products include PhoneSweep, a commercial telephone line scanner and NetIntercept, a network analysis tool to reassemble TCP sessions and reconstruct files.

SecurDesk (www.cursorarts.com/ca_sd.html): Access control and verification, protection for sensitive files and folders, log usage, customizable desktop environment, administration, and limit use.

Secure Directory File Transfer System (www.owlcti.com/): An essential tool for organizations that demand the ultimate in security. This "special purpose firewall" will safeguard the privacy of your data residing on a private network, while at the same time, providing an inflow of information from the Internet or any other outside network.

Secure your PC (www.maths.usyd.edu.au/u/psz/securepc.html): A few notes on securing a Windows98 PC.

Security Awareness, Inc. (www.securityawareness.com/): Security awareness products for all types of organizations, including security brochures, custom screensavers, brochures and computer-based training.

Security Officers Management and Analysis Project (www.somap.org/): An Open Source collaborative project building an information security risk management method, manuals and toolset.

SecurityFriday Co. Ltd. (www.securityfriday.com/): Software to monitor access to Windows file servers, detect promiscuous mode network sniffers and quantify password strength.

SeQureIT (www.softcat.com/): Security solutions including WatchGuard firewalls, Check Point, Clearswift, Nokia and Netilla SSL VPN. Also provide managed and professional services.

Service Strategies Inc. (www.ssimail.com/): Email gateway and messaging, firewall, VPN and SSL software and appliances for AS/400 and PC networks.

Silanis Technology (www.silanis.com/index.html): Electronic and digital signature solution provider includes resources, white papers, product news and related information.

Simpliciti (simpliciti.biz/): Browser lockdown software to restrict Web browsing.

Smart PC Tools (www.smartpctools.com/en/index.html): Offers a range of PC software products, most of which relate to security.

Softcat plc (UK) (www.softcat.com/): Supplier of IT solutions, dealing with software, hardware and licensing.

Softek Limited (www.mailmarshal.co.uk/): Distributor of security software: anti-virus, anti-spam, firewall, VPN, Web filtering, USB device control etc.

Softnet Security (www.safeit.com/): Software to protect confidential communication and information. Product specifications, screenshots, demo downloads, and contact details.

Tech Assist, Inc. (www.toolsthatwork.com/): Applications for data recovery, network security, and computer investigation.

Tropical Software (www.tropsoft.com/): Security and Privacy products.

UpdateEXPERT (www.lyonware.co.uk/Update-Expert.htm): A hotfix and service pack security management utility that helps systems administrators keep their hotfixes and service packs up-to-date.

Visionsoft (www.visionsoft.com/): Range of security and software license auditing software for businesses, schools and personal users.

Wave Systems Corp. (www.wavesys.com/): Develops proprietary application specific integrated circuit which meters usage of data, graphics, software, and video and audio sequences which can be digitally transmitted and develops a software version of its application for use over the Internet. (Nasdaq: WAVX).

WhiteCanyon Security Software (www.whitecanyon.com/): Providing software products to securely clean, erase, and wipe electronic data from hard drives and removable media.

Wick Hill Group (www.wickhill.co.uk/): Value added distributor specializing in secure infrastructure solutions for ebusiness. Portfolio includes a range of security solutions, from firewalls to SSL VPN, as well as Web access and Web management products.

Winability Software Corporation (www.winability.com/home/): Directory access control and inactivity timeout software for Windows systems.

xDefenders Inc. (www.xdefenders.com/): Security appliances combining spam, virus and Web content filtering with firewall and IDS systems, plus vulnerability assessment services.

ZEPKO (www.zepko.com/): SIM (Security Information Management) technology provider. Assessing business risks and technology vulnerabilities surrounding IT security products.

9. RESEARCH

Centre for Applied Cryptographic Research (www.cacr.math.uwaterloo.ca/): Cryptographic research organization at the University of Waterloo. Downloads of technical reports, upcoming conferences list and details of graduate courses available.

Cryptography Research, Inc (www.cryptography.com/): Research and system design in areas including tamper resistance, content protection, network security, and financial services. Service descriptions and white papers.

Dartmouth College Institute for Security Technology Studies (ISTS) (www.ists.dartmouth.edu/): Research group focusing on United States national cyber-security and technological counterterrorism. Administers the I3P consortium.

Penn State S2 Group (ist.psu.edu/s2/): General cyber security lab at the United States university. Includes current and past projects, software, publications, and events.

The SANS Institute (www.sans.org/): Offers computer security research, training and information.

SUNY Stony Brook Secure Systems Lab (seclab.cs.sunysb.edu/seclab1/): Group aimed at research and education in computer and network security. Projects, academic programs, and publications. Located in New York, United States.

10. CONTENT FILTERING LINKS

Content Filtering vs. Blocking (www.securitysoft.com/content_filtering.html): An interesting whitepaper from Security Software Systems discussing the pros and cons of content filtering and blocking.

GateFilter Plug-in (www.deerfield.com/products/gate-filter/): GateFilter Plug-in is a software Internet filter providing content filtering for WinGate. The plug-in uses technology based on Artificial Content Recognition (ACR), which analyzes the content of a Web site, determines if it is inappropriate, and blocks the site if necessary. Supports English, German, French, and Spanish.

GFI Mail Essentials (www.gfi.com/mes/): Mail Essentials provides email content checking, antivirus software, and spam blocking for Microsoft Exchange and SMTP.

InterScan eManager (us.trendmicro.com/us/solutions/enterprise/security-solutions/web-security/index.html): Provides real-time content filtering, spam blocking, and reporting. Optional eManager plug-in integrates seamlessly with InterScan VirusWall to safeguard intellectual property and confidential information, block inappropriate email and attachments, and protect against viruses. eManager also enables Trend Micro Outbreak Prevention Services.

NetIQ (MailMarshal) (www.marshal.com/): NetIQ provides MailMarshal, imMarshal, and WebMarshal for content filtering coupled with antivirus protection (McAfee).

Postfix Add-on Software (www.postfix.org/addon.html): List and links of add-on software for Postfix, including content filtering and antivirus solutions.

Qmail-Content filtering (www.fehcom.de/qmail/filter.html): Scripts that provide content filtering for incoming email with Qmail.

SonicWALL's Content Filtering Subscription Service (www.sonicguard.com/ContentFilteringService.asp): Integrated with SonicWALL's line of Internet security appliances, the Sonic WALL Content Filtering subscription enables organizations such as businesses, schools and libraries to maintain Internet access policies tailored to their specific needs.

SurfControl (www.websense.com/site/scwelcome/index.html): SurfControl is a London-based company providing email and Web filtering solutions. as well as

Internet monitoring and policy management software. Recently purchased by Websense.

Tumbleweed (www.tumbleweed.com/): Tumbleweed provides secure messaging and email policy management solutions geared to the government, financial and healthcare industries.

WebSense (www.websense.com/content/home.aspx): Websense provides a wide range of solutions including Internet filters, monitoring software, content filtering, tracking, and policy management.

11. OTHER LOGGING RESOURCES

IETF Security Issues in Network Event Logging (www.ietf.org/html.charters/syslog-charter.html): USENIX Special Interest Group.

Building a Logging Infrastructure (www.sage.org/pubs/12_logging/): Loganalysis.org is a volunteer not-for-profit organization devoted to furthering the state of the art in computer systems log analysis through dissemination of information and sharing of resources.

Warning: URLs may change or be deleted without notice.

Ensuring Built-in Frequency Hopping Spread Spectrum Wireless Network Security

The Sensors Directorate sponsored new technology developed by Robert Gold Comm Systems, Inc. (RGCS) under a Phase II Fast Track Small Business Innovation Research program. This technology provides powerful security protection for wireless computer networks, cell phones, and other radio communications. Benefits include highly secure communications with the overhead of encryption and selective addressability of receivers, individually or in groups.[1]

1. ACCOMPLISHMENT

Dr. Gold developed a built-in self-synchronizing and selective addressing algorithm based on times-of-arrival (TOA) measurements of a frequency-hopping radio system. These algorithms allow a monitor to synchronize to a frequency-hopping radio in a wireless network by making relatively brief observations of the TOAs on a single frequency. RGCS designed the algorithms for integration into spread-spectrum, frequency-hopping systems widely used for wireless communications such as wireless fidelity computer networks, cellular phones, and two-way radios used by the military, police, firefighters, ambulances, and commercial fleets.[1]

2. BACKGROUND

Although very convenient for users, wireless communication is extremely vulnerable to eavesdropping. For example, hackers frequently access wireless computer networks (laptop computers linking to the wireless network).[1]

Encrypting the data increases the security of these wireless networks, but encryption is complex, inconvenient, time consuming for users, and adds a significant amount of overhead information that reduces data throughput. In frequency-hopping (spread-spectrum) wireless networks now in wide use, users protect the data by sending it in brief spurts, with the transmitter and receiver skipping in a synchronized pattern among hundreds of frequencies. An intruder without knowledge of the synchronization pattern would just hear static.[1]

A major vulnerability of many spread-spectrum wireless networks involves compromising the network security by intercepting unprotected information. Originators must send the sync pattern information to authorized receivers, often unprotected.[1]

The Gold algorithms support code-division multiple access, frequency-hopping multiple access, and ultra-wide-band spread-spectrum communication systems. They are designed for incorporation into enhanced versions of existing products, most of which already include circuitry that manufacturers can adapt to implement the technology.[1]

3. ADDITIONAL INFORMATION

To receive more information about the preceding or other activities in the Air Force Research Laboratory, contact TECH CONNECT, AFRL/XPTC, (800) 203−6451, and you will be directed to the appropriate laboratory expert. (03-SN-21).[1]

Configuring Wireless Internet Security Remote Access

This Appendix describes how to configure and add wireless remote access points (APs) as RADIUS clients of the Microsoft 2003 and Vista Internet Authentication Service (IAS) servers.

ADDING THE ACCESS POINTS AS RADIUS CLIENTS TO IAS

You must add wireless remote APs as RADIUS clients to IAS before they are allowed to use RADIUS authentication and accounting services. The wireless remote APs at a given location will typically be configured to use an IAS server at the same location for their primary RADIUS server and another IAS server at the same or a different location as the secondary RADIUS server. The terms "primary" and "secondary" here do not refer to any hierarchical relationship, or difference in configuration, between the IAS servers themselves. The terms are relevant only to the wireless remote APs, each of which has a designated primary and secondary (or backup) RADIUS server. Before you configure your wireless remote APs, you must decide which IAS server will be the primary and which will be the secondary RADIUS server for each wireless remote AP[1].

The following procedures describe adding RADIUS clients to two IAS servers. During the first procedure, a RADIUS secret is generated for the wireless remote AP; this secret, or key, will be used by IAS and the AP to authenticate each other. The details of this client along with its secret are logged to a file. This file is used in the second procedure to import the client into the second IAS[1].

Tip: You must not use this first procedure to add the same client to two IAS servers. If you do this, the client entries on each server will have a different RADIUS secret configured and the wireless remote AP will not be able to authenticate to both servers.

ADDING ACCESS POINTS TO THE FIRST IAS SERVER

This part of the appendix describes the adding of wireless remote APs to the first IAS server. A script is supplied to automate the generation of a strong, random RADIUS secret (password) and add the client to IAS. The script also creates a file (defaults to Clients.txt) that logs the details of each wireless remote AP added. This file records the name, IP address, and RADIUS secret generated for each wireless remote AP. These will be required when configuring the second IAS server and wireless remote APs[1].

Tip: The RADIUS clients are added to IAS as "RADIUS Standard" clients. Although this is appropriate for most wireless remote APs, some APs may require that you configure vendor–specific attributes (VSA) on the IAS server. You can configure VSAs either by selecting a specific vendor device in the properties of the RADIUS clients in the Internet Authentication Service MMC or (if the device is not listed) by specifying the VSAs in the IAS remote access policy.

SCRIPTING THE ADDITION OF ACCESS POINTS TO IAS SERVER (ALTERNATIVE PROCEDURE)

If you do not want to add the wireless remote APs to the IAS server interactively using the previous procedure, you can just generate the RADIUS client entries output files for each wireless remote AP without adding them to IAS. You can then import the RADIUS client entries into both the first IAS server and the second IAS server. Because you can script this whole operation, you may prefer to add your RADIUS clients this way if you have to add a large number of wireless remote APs[1].

Tip: This procedure is an alternative method for adding RADIUS clients in a scripted rather than an interactive fashion.

1. "Securing Wireless LANs with PEAP and Passwords, Chapter 5: Building the Wireless LAN Security Infrastructure," © 2008 Microsoft Corporation. All rights reserved. Microsoft Corporation, One Mcrosoft Way, Redmond, WA 98052-6399, 2007.

CONFIGURING THE WIRELESS ACCESS POINTS

Having added RADIUS clients entries for the wireless remote APs to IAS, you now need to configure the wireless remote APs themselves. You must add the IP addresses of the IAS servers and the RADIUS client secrets that each AP will use to communicate securely with the IAS servers. Every wireless remote AP will be configured with a primary and secondary (or backup) IAS server. You should perform the procedures for the wireless remote APs at every site in your enterprise[1].

The procedure for configuring wireless remote APs varies depending on the make and model of the device. However, wireless remote AP vendors normally provide detailed instructions for configuring their devices. Depending on the vendor, these instructions may also be available online[1].

Prior to configuring the security settings for your wireless remote APs, you must configure the basic wireless network settings. These will include but are not limited to:

- IP Address and subnet mask of the wireless remote AP
- Default gateway
- Friendly name of the wireless remote AP
- Wireless Network Name (SSID)[1]

The preceding list will include a number of other parameters that affect the deployment of multiple wireless remote APs: settings that control the correct radio coverage across your site, for example, 802.11 Radio Channel, Transmission Rate, and Transmission Power, and so forth. Discussion of these parameters is outside the scope of this appendix. Use the vendor documentation as a reference when configuring these settings or consult a wireless network services supplier[1].

The guidance in this appendix assumes that you have set these items correctly and are able to connect to the wireless remote AP from a WLAN client using an unauthenticated connection. You should test this before configuring the authentication and security parameters listed later in this appendix[1].

TABLE eH.1 Wireless Access Point Configuration

Item	Setting
Authentication Parameters	
Authentication Mode	802.1 X Authentication
Re-authentication	Enable
Rapid/Dynamic Re-keying	Enable
Key Refresh Time-out	60 minutes
Encryption Parameters (these settings usually relate to static WEP encryption)	(Encryption parameters may be disabled or be overridden when rapid re-keying is enabled)
Enable Encryption	Enable
Deny Unencrypted	Enable
RADIUS Authentication	
Enable RADIUS Authentication	Enable
Primary RADIUS Authentication Server	Primary IAS IP Address
Primary RADIUS Server Port	1812 (default)
Secondary RADIUS Authentication Server	Secondary IAS IP Address
Secondary RADIUS Server Port	1812 (default)
RADIUS Authentication Shared Secret	XXXXXX (replace with generated secret)
Retry Limit	5
Retry Timeout	5 seconds
RADIUS Accounting	
Enable RADIUS Accounting	Enable
Primary RADIUS Accounting Server	Primary IAS IP Address
Primary RADIUS Server Port	1813 (default)
Secondary RADIUS Accounting Server	Secondary IAS IP Address
Secondary RADIUS Server Port	1813 (default)
RADIUS Accounting Shared Secret	XXXXXX (replace with generated secret)
Retry Limit	5
Retry Timeout	5 seconds

ENABLING SECURE WLAN AUTHENTICATION ON ACCESS POINTS

You must configure each wireless remote AP with a primary and a secondary RADIUS server. The wireless remote AP will normally use the primary server for all authentication requests, and switch over to the secondary server if the primary server is unavailable. It is important that you plan the allocation of wireless remote APs and carefully decide which server should be made primary and which should be made secondary. To summarize:

In a site with two (or more) IAS servers, balance your wireless remote APs across the available servers so that approximately half of the wireless remote APs use server

TABLE eH.2 Wireless Access Point Security Configuration

Item	Recommended Setting	Notes
General		
Administrator Password	xxxxxx	Set to complex password.
Other Management Passwords	xxxxxx	Some devices use multiple management passwords to help protect access using different management protocols; ensure that all are changed from the defaults to secure values.
Management Protocols		
Serial Console	Enable	If no encrypted protocols are available, this is the most secure method of configuring wireless remote APs although this requires physical serial cable connections between the wireless remote APs and terminal and hence cannot be used remotely.
Telnet	Disable	All Telnet transmissions are in plaintext, so passwords and RADIUS client secrets will be visible on the network. If the Telnet traffic can be secured using Internet Protocol security (IPsec) or SSH, you can safely enable and use it.
HTTP	Disable	HTTP management is usually in plaintext and suffers from the same weaknesses as unencrypted telnet. HTTPS, if available, is recommended.
HTTPS(SSL or TLS)	Enable	Follow the vendor's instructions for configuring keys/certificates for this.
SNMP Communities		SNMP is the default protocol for network management. Use SNMP v3 with password protection for highest security. It is often the protocol used by GUI configuration tools and network management systems. However, you can disable it if you do not use it.
Community 1 Name	XXXXXX	The default is usually "public." Change this to a complex value.
Community 2 Name	Disabled	Any unnecessary community names should be disabled or set to complex values.

1 as primary and server 2 as secondary, and the remaining use server 2 as primary and server 1 as secondary[1].

In sites where you have only one IAS server, this should always be the primary server. You should configure a remote server (in the site with most reliable connectivity to this site) as the secondary server[1].

In sites where there is no IAS server, balance the wireless remote APs between remote servers using the server with most resilient and lowest latency connectivity. Ideally, these servers should be at different sites unless you have resilient wide area network (WAN) connectivity[1].

Table eH.1[1] lists the settings that you need to configure on your wireless remote APs. Although the names and descriptions of these settings may vary from one vendor to another, your wireless remote AP documentation helps you determine those that correspond to the items in Table H.1[1].

Tip: The Key Refresh Time-out is set to 60 minutes for use with dynamic WEP. The Session Timeout value set in the IAS remote access policy is the same or shorter than this. Whichever of these has the lower setting will take precedence, so you only need to modify the setting in IAS. If you are using WPA, you should increase this setting in the AP to eight hours. Consult your vendor's documentation for more information.

Use the same RADIUS secrets procedure to add wireless remote APs to IAS. Although you may have not yet configured a secondary IAS server as a backup to the primary server, you can still add the server's IP address to the wireless remote AP now (to avoid having to reconfigure it later)[1].

Depending on the wireless remote AP hardware model, you may not have separate configurable entries for Authentication and Accounting RADIUS servers. If you have separate configurable entries, set them both to the same server unless you have a specific reason for doing otherwise. The RADIUS retry limit and timeout values given in Table H.1 are common defaults but these values are not mandatory[1].

> *Note:* If you are currently using wireless remote APs with no security enabled or only static WEP, you need to plan your migration to an 802.1 X–based WLAN.

ADDITIONAL SETTINGS TO SECURE WIRELESS ACCESS POINTS

In addition to enabling 802. 1X parameters, you should also configure the wireless remote APs for highest security. Most wireless network hardware is supplied with insecure management protocols enabled and administrator passwords set to well-known defaults, which poses a security risk. You should configure the settings listed in Table eH.2[1]; however, this is not an exhaustive list. You should consult your vendor's documentation for authoritative guidance on this topic. When choosing passwords and community names for Simple Network Management Protocol (SNMP), use complex values that include upper and lowercase letters, numbers, and punctuation characters. Avoid choosing anything that can be guessed easily from information such as your domain name, company name, and site address[1].

You should not disable SSID (WLAN network name) broadcast since this can interfere with the ability of Windows XP to connect to the right network. Although disabling the SSID broadcast is often recommended as a security measure, it gives little practical security benefit if a secure 802.1X authentication method is being used. Even with SSID broadcast from the AP disabled, it is relatively easy for an attacker to determine the SSID by capturing client connection packets. If you are concerned about broadcasting the existence of your WLAN, you can use a generic name for your SSID, which will not be attributable to your enterprise[1].

REPLICATING RADIUS CLIENT CONFIGURATION TO OTHER IAS SERVERS

Typically, the wireless remote APs in a given site are serviced by an IAS server at that site. For example, the site A IAS server services wireless remote APs in site A, while the site B server services wireless remote APs in site B and so on. However, other server settings such as the remote access policies will often be common to many IAS servers. For this reason the export and import of RADIUS client information is handled separately by the procedures described in this appendix. Although you will find relatively few scenarios where replicating RADIUS client information is relevant, it is useful in certain circumstances (for example, where you have two IAS servers on the same site acting as primary and secondary RADIUS servers for all wireless remote APs on that site)[1].

Appendix eI

Frequently Asked Questions

Q. What is a firewall?

A. Firewall helps make your computer invisible to online attackers and blocks some malicious software such as viruses, worms, and Trojans. A firewall can also help prevent software on your computer from accessing the Internet to accept updates and modification without your permission[1].

Firewalls come in both software and hardware form, but hardware firewalls are intended for use *in addition* to a software firewall. It is important to have both a firewall and antivirus software turned on before you connect to the Internet[1].

Q. What is antivirus software?

A. Antivirus software helps protect your computer against *specific* viruses and related malicious software, such as worms and Trojans. Antivirus software must be kept up to date. Updates are generally available through a subscription from your antivirus vendor[1].

Q. Do you need both a firewall and antivirus software?

A. Yes. A firewall helps stop hackers and viruses before they reach your computer, while antivirus software helps get rid of known viruses if they manage to bypass the firewall or if they've already infected your computer. One way viruses get past a firewall is when you ignore its warning messages when you download software from the Internet or email[1].

Q. What is antispyware software?

A. Antispyware software helps detect and remove spyware from your computer. "Spyware" (also known as "adware") generally refers to software that is designed to monitor your activities on your computer[1].

Spyware can produce unwanted pop-up advertising, collect personal information about you, or change the configuration of your computer to the spyware designer's specifications. At its worst, spyware can enable criminals to disable your computer and steal your identity. Antispyware software is an important tool to help you keep your computer running properly and free from intrusion[1].

Note: Some "spyware" actually helps desirable software to run as it's intended, or enables some good software to be offered on a free-with-advertisements basis (such as many online email programs). Most antispyware software allows you to customize your settings so you can enable or disable programs.

Q. What is a spam filter?

A. Spam filters (sometimes broadly referred to as "email filters") evaluate incoming email messages to determine if they contain elements that are commonly associated with unwanted or dangerous bulk mailing. If the filter determines that an email message is suspicious, the message usually goes to a designated folder, and links and other code in it are disabled. Then you can evaluate the message more safely at your convenience[1].

Q. What is a phishing filter?

A. A phishing filter is usually a component of a Web browser or Internet toolbar. It evaluates Web sites for signs that they are connected with phishing scams.

Phishing scams use email and Web sites that look identical to those that belong to legitimate sources (such as financial or government institutions) but are actually hoaxes. If you click links in the email or enter your user name, password, and other data into these Web sites, it gives scammers information they can use to defraud you or to steal your identity[1].

Q. What are parental controls?

A. Parental controls can help you protect your children from inappropriate content, both on the Internet and in computer video games[1].

Q. Does my brand new computer come with these software security tools?

A. Maybe. When you buy a new computer, check your packing list to see if the manufacturer has included firewall, antivirus, or antispyware software in addition to the operating system[1].

Case Studies

1. CASE STUDY 1: SSL VPN SOLUTION PLANNING AND IMPLEMENTATION

This case study presents SSL VPN solution planning and implementation. The case study begins by describing a real-world security requirement scenario: protecting network communications between remote users and a main office. The case study then discusses possible solutions for the security requirement and explains why an SSL VPN architecture was selected over the alternatives. The next part of the case study discusses the design of the solution and also provides some details of the implementation of the solution prototype, including examples of configuring the solution using commonly available equipment and software.

The case study is not meant to endorse the use of particular products, nor are any products being recommended over other products. A fictional combination of several common products was chosen so that the case study would demonstrate a variety of solutions. Organizations and individuals should not replicate and deploy the sample entries. They are intended to illustrate the decisions and actions involved in configuring the solutions, not to be deployed as-is into systems.

The organization already offers remote access services in the form of a host-to-gateway IPsec solution. This works successfully but has required significant IT labor resources to install and support the client software on user hosts. The current solution also does not provide remote access for hosts based in public locations such as hotels and kiosks. The organization is therefore looking to implement a complementary remote access architecture.

2. CHALLENGES

The organization specifies its organizational requirements for remote access:

- All users should have access to all internal network resources, especially email and calendar services. This open policy is necessary because of the broad range of IT resources required by users to conduct their research. Users may also be required to authenticate themselves to specific resources such as file shares and databases.
- Users should only have access to a limited set of internal services such as email and calendaring if they are using public hosts (hosts located in environments such as hotels and Internet cafes).
- A small population of users outside of the organization and human resources (HR) staff from the parent organization, should have access to a limited set of internal HR applications.

3. SOLUTION

Network Layer Solution: IPsec VPN

As previously mentioned, the organization has already established IPsec-based network layer VPN services for remote users. Many users are satisfied with this solution, but it can be cumbersome for IT staff to support because each host requires client software to be installed and supported. Moreover, hosts without the preinstalled client software cannot access internal resources.

Transport Layer Solution: SSL VPN

The organization could provide an SSL VPN between the remote users and the office over the Internet. Network extension is the most flexible option because it provides broad access for users into an internal network.

Application Layer Solution: Application Modification

The organization could modify every application required for remote access. Applications such as SSH are already supported for remote access. Due to the broad range of relevant applications, it is not considered feasible to modify all of them.

The organization decides to develop an SSL VPN solution. This solution will complement and not replace the existing IPsec VPN services. It is assumed that some users will stay with the IPsec solution, but others will migrate to SSL VPN over time. The organization purchases a commercial appliance with a support contract to ensure the existence of vendor support.

Designing the Solution

The organization goes through a process to design the SSL VPN solution. It first designs an access control policy to determine who can access internal resources and under what conditions. The next step is to create an endpoint security policy that enforces access control, usually with host integrity checks. Creating an authentication infrastructure, designing the architecture and deciding on encryption, are the last steps.

Access Control Policy

The organization goes through the four major steps to designing an access control policy:

1. **List the resources that will be accessed through the SSL VPN.** Users should have access to all internal network resources, so these resources can all be grouped together. If a specific resource such as a file share or database requires additional authentication, then this takes place when a user accesses the resource. The only exception to this policy of grouping all resources is a set of HR applications that only a small set of external users is authorized to access. Note that these users may not access the other internal resources that other users can access.
2. **List the groups or users.** Most users are in one main group that has network connectivity to all internal resources. A smaller group is composed of external users that have access to the set of HR applications mentioned in the previous step.
3. **List the conditions under which the resources should be accessible by the groups.** There are several conditions for accessing resources:
   - Users must use hosts managed by the organization to gain access to internal resources. These organization-managed hosts all have a system registry key installed that can be checked to verify their identity.
   - Users who login from systems in a public location such as a kiosk or Internet café or use their personal computers can only access a limited set of Web-based applications such as email, calendaring, and employee phone directory.
   - The small group of external users that access the HR applications must also use organization-managed hosts to gain access to these applications.
   - All hosts, public or otherwise, must be running the latest version of Windows with critical security updates installed and an antivirus package with an up-to-date virus signature database. They must also have a firewall program installed and running. Any host not meeting these requirements is not permitted to login.
4. **List how the VPN should be used to access the resources.** Resources are accessible in different ways:
   - The organization's internal resources are accessible by network extension because a broad number of them are hosted on multiple servers. Also, some Web-based applications do not function properly when proxying is used, so network extension must be used.
   - When users login from public hosts that are not organization-managed, they can access a set of Web-based applications via proxy.
   - The set of HR applications are accessible by network extension because some require many interlocking programs and cannot be accessed by other means.

Endpoint Security Policy

The organization designs an endpoint security policy to enforce access control. The policy is mainly driven by a prelogin sequence executed by the SSL VPN appliance before a user logs in. This sequence runs host integrity checks that require the host to download and run active content controls. These controls or applets ensure that the host complies with the organization's endpoint security policy.

The endpoint security policy is based on the access control policy and elaborates further: An organization-managed host is identified by a registry key indicating that the host is managed by the organization. The host integrity check only needs to find this key to verify the host's identity. Organization-managed hosts use network extension to gain full access to the internal network. A packet filter is configured on the SSL VPN to prevent these hosts from accessing the restricted set of HR applications. If a user is permitted to use the restricted set of HR applications, a packet filter is configured on the SSL VPN to prevent the user from accessing any resource outside the HR applications. Users are permitted to keep all cookies, Web browser cache entries, and downloaded files and attachments.

A host that is not organization-managed or is personally owned can only access Web applications via proxy. The SSL VPN session is established in a virtual storage space and all data stored or downloaded during the session is erased after logout.

All hosts must run one or more specific versions of Windows, with each specific version using the most current set of updates. Critical security updates are also required to be installed. The host must run an antivirus software program certified by the organization that is active and uses a virus signature database that has been updated in the past month. The host must also run a firewall program.

Authentication Scheme

The organization has an existing RADIUS authentication infrastructure for multiple resources such as databases and email servers. The SSL VPN appliances use the same RADIUS servers to authenticate users as they login to the SSL VPN portal. The groups that are defined by the access control policy are configured in RADIUS. So most users belong to one large RADIUS group, and the external users granted access to the HR applications are put into another smaller RADIUS group.

The SSL VPN appliances determine this group information from RADIUS so they can dynamically map users into the correct group. For example, a user who is a member of the HR Users' RADIUS group is only given access to the HR applications.

Users authenticate themselves via two-factor authentication. Each user must type in a password and use a physical token to enter a one-time password generated by the token. For server authentication, the organization purchases an SSL server certificate from a CA whose root certificate is already installed in most common browsers and installs the SSL server certificate on the SSL VPN appliance.

Architecture Design

The organization designs an architecture incorporating the SSL VPN appliances within its existing network infrastructure. It performs configuration of the appliances and devises a management policy.

Selection of Hardware Configuration

The organization chooses an appliance solution developed by a commercial vendor. Hardware appliances are the most common type of SSL VPN hardware on the market today, and they possess the advantages of being preconfigured and already hardened by the vendor. Furthermore, support is more straightforward because the device configuration is standardized.

Device Placement and Firewall Configuration

The organization adopts an internal SSL VPN approach for device placement. Access to TCP port 443 on the SSL VPN for all external addresses is added to the corporate firewall; no other access rules are added to the firewall.

Routing Policy

The organization prohibits split tunneling, so the remote access host sends all traffic destined for internal subnets and the rest of the Internet through the VPN tunnel. Traffic destined for machines outside the organization's perimeter is blocked by the SSL VPN. In this case, attempts to go off the corporate network directly from the user's system are blocked. Some SSL VPNs include *hairpin proxies* that allow VPN users to leave the network, but only by traversing the SSL VPN gateway, which has been set up as a normal outgoing firewall.

The organization has a main headquarters location and several branch offices, but it only deploys SSL VPN appliances at headquarters. All of the organization's internal IT resources are available at headquarters.

High Availability

The organization is pursuing a high availability strategy. The VPN appliance supports high availability with an active/passive architecture. Configuration settings are mirrored across both devices, so any configuration change made to the active device is automatically copied to the passive device's configuration. VPN session information is also mirrored; users do not have to reauthenticate after a device failure, but existing TCP connections are broken and do have to be reestablished.

Management

The management policy for the VPN appliances is consistent with the organization's security policy. Administrative access is only supported on the appliance's internal interface and is limited to a small set of IP addresses. Accounts with limited administrative access are created and assigned to different groups, such as one account that can review system logs and another account that can update the host integrity checks to search for recent security updates.

Configuration settings are backed up each week to a central server. The organization also uses a set of appliances for testing and staging. They are configured identically to the live units, and any updates or patches are applied on them first.

The appliances are monitored by the organization's network management system. The network management system periodically pings the appliances' IP addresses and polls the appliances' SNMP management information base (MIB). It compares data from the MIB with known operational values to search for any potential operational issues.

Client Software Selection

The prelogin sequence requires a remote access host to download and execute active content so the host integrity checks can be performed. The desktop management policies for the organization-managed hosts are configured to permit specific active content controls to run locally.

Portal Design

The organization uses the portal provided by the VPN appliance vendor. It provides some customization such as altering the banner graphics to be consistent with the organization's logo and colors. It also only displays options that the user is authorized to access. For example, if a user is in the group that is only allowed to view the HR Web sites, only those sites are listed on the user's portal page.

Encryption Scheme

The organization requires FIPS 140-2 compliance for its SSL VPN solution. As a result, the organization verifies the level of FIPS compliance of the system before purchasing it. The organization configures the SSL VPN to only permit logins from client browsers that use SSL cipher suites with FIPS-approved cryptography. The appliance is also configured to require browsers to support TLS 1.0 or higher for SSL connections.

Implementing a Prototype

After the organization designs the SSL VPN solution, it implements and tests a prototype of the design. The prototype is initially configured and tested in a laboratory network and is moved later to a production network so access to actual internal resources can be tested. The laboratory network replicates the addresses of the corporate network, and thus needs to be completely unconnected to the corporate network. The test network includes a firewall with the same configuration as the corporate firewall, and example servers that have the same capabilities and the same addresses as the servers that will be accessed through the SSL VPN.

The organization develops a test plan to evaluate functionality and connectivity. The plan includes tests for connectivity, authentication, access control, endpoint security, and client interoperability. Users of multiple operating systems (Windows, Linux, Macintosh), device types (laptops, PDAs, smart phones) and Web browsers (Internet Explorer, Firefox, Mozilla, Safari) must be able to access internal resources from outside the network. If users are using organization-managed hosts, then they should be able to do everything they could do if they were located in their offices. Multiple scenarios such as a user logging in from a public host or a host that has an out of date virus database must be tested. The testers also validate that people with different types of RADIUS credentials only get the expected type of access when they log in during the test.

Example Configuration Steps

Different SSL VPNs have different administrative interfaces. Many allow control through Web browsers, while some use custom programs, and still others use old-style command line interfaces (CLI). In this part, a fictitious SSL VPN that has a browser interface is described along with examples of steps that might be taken to implement the rules from the scenario. The interface has four major sections:

1. System
2. Users
3. Access
4. Policies.

To begin, the administrator needs to configure the addresses of the Ethernet interface on the SSL VPN. The administrator goes to the *Ethernet* choice in the System menu and sets the address assigned to the SSL VPN on the inside of the corporate network. Because this system is configured inside the existing network, no routing needs to be defined; had this SSL VPN been located outside the firewall or on the DMZ, the administrator would need to specify routing information.

Using the *Add User Group* choice of the Users menu, the administrator creates a group called "NormalUsers". In this dialog box, the administrator specifies which authentication mechanisms are used (a password and a physical token) and specifies how the authentication is validated (using the existing RADIUS server). The administrator specifies that participation in the NormalUsers group for the VPN is given to people whom the RADIUS server labels as "User". They use the Add User Group choice to add a second group, "HROnlyUsers", but participation in that group is the people the RADIUS server labels as "HR Users".

The Access menu allows the administrator to define those resources to which the members of each user group have access. Using the *Add Access Group* command, the administrator creates an access group called "NormalFullAccess" that links "NormalUsers" to all network services, using a network extension program from the SSL VPN. The network extension's packet filter is set up to block TCP ports 80 and 443 of the addresses of the Web servers that are controlled by the HR department. The administrator also selects *only display available resources* for this access group.

Next, for users accessing the SSL VPN from equipment that is not owned by the organization, the administrator uses the *Add Access Group* command to create an access group called "NormalPartialAccess" that links "NormalUsers" only to TCP port 80 of the addresses for the three Web servers that have the corporate calendar, the Web mail system, and the employee phone directory,

using a reverse Web proxy, and selects only *display available resources*. Last, the administrator creates the "HRAccess" group that links "HROnlyUsers", using a network extension program from the SSL VPN to allow access to only TCP ports 80 and 443 of the addresses of the Web servers that are controlled by the HR department, and selects *only display available resources*.

The three access lists each have policies associated with them, so the administrator uses the *Policy List* command in the *Policies* menu to create a list of policies. The dialog box starts with an empty list, and the administrator clicks the *Add* button to create the first policy. In that dialog box, the administrator specifies that everyone in the NormalFullAccess group must use the following policies:

- The remote host is managed by the organization.
- The latest version of one or more specific versions of Windows is being used.
- The most current set of patches and security updates has been applied to the operating system.
- An approved antivirus program is running.
- An approved firewall program with an approved configuration is running.
- Split tunneling is not permitted.
- The protocol used must be TLS 1.0 or later.

The cryptographic protocol being used must be one that complies with FIPS 140-2. After creating this policy, the administrator creates similar policies for everyone in the NormalPartialAccess and HRAccess groups.

The last steps are to configure the management of the SSL VPN itself. In the *Administrators* command in the System menu, the administrator changes the default password that came with the system and sets the range of IP addresses that can be used to administer the system. In the same dialog box, the administrator also creates additional administrative accounts with limited rights, such as for viewing particular logs. Under the *Backup* command in the System menu, the administrator sets up automatic weekly backups to be sent to an FTP server on the internal network. The *SNMP* command in the System menu is used to allow monitoring of the device.

The *Replication* command in the System menu allows configuration of the high availability feature described earlier. The administrator enters the address of the other server in the high availability group and specifies that this server is the "master" of the group.

Deploying and Managing the Solution

The organization employs a pilot program to deploy the solution. It solicits volunteers who can contribute their user experience and help to troubleshoot any problems with connectivity or interoperability. The SSL VPN development staff also produces documentation to help in establishing VPN connectivity. The documentation assists users in enabling the host integrity checks to be executed on their hosts, and it addresses frequently asked questions.

Conclusion

This case study covered planning and implementing an SSL VPN system for an organization. The steps described in this case study follow the recommendations and guidelines given for choosing and setting up an SSL VPN. It should be emphasized that the scenario described in this case study is for a fictitious organization and that the steps taken by a real organization would likely be different from those given here.

The portrayed organization first identified its needs based on its current operations and its stated future goals for secure remote access. In designing the proposed solution, the organization followed the typical steps of creating both an access control and an endpoint security policy: laying out its methods for authentication of users; designing an overall architecture for the expected remote access solution; selecting the hardware needed to meet its goals; specifying where in its current network the hardware will go; determining whether or not it needs a high availability solution; creating a management policy for the system and users; selecting the client software; designing the portal that the users will see when they connect to the system; and, developing an encryption policy.

After this design was completed, the organization implemented a prototype of the system before deploying it fully. The test plan for this prototype involved creating a sample configuration for the network access, the list of users for the system, definitions of the types of access that will be given to the users, and a specific policy plan linking the users to the types of access as well as other policy restrictions on the users.

4. CASE STUDY 2: CYBER ATTACKS ON CRITICAL INFRASTRUCTURES—A RISK TO THE NATION

There has been a great deal of research related to cyber attacks and vulnerabilities and critical infrastructure, but there is an incomplete understanding of the cascading effects a cyber-caused disruption could have on other critical national infrastructures and the ability of the affected infrastructures to deliver services. Sandia National Laboratories (Sandia) has developed methodologies that translate a cyber-based disruption to a physical disruption of infrastructure and economic methodologies that can provide an understanding of the national-level risk from cyber attacks on critical infrastructure. This case study

discusses these methodologies, and addresses these methods' gaps for correlating cyber attacks with physical and economic consequences in the nation's critical infrastructures. This case study further explains Sandia's roadmap to fill the methodological gaps, beginning with the electric power grid and then extending to other infrastructures.

5. CHALLENGES

This part of the case study describes a cyber-attack-consequence assessment process developed to coordinate Sandia's capabilities in assessing the effects of a cyber attack and in assessing the infrastructure impacts and economic consequences of those attacks.

Step 1 of this process identifies a cyber attack, and Step 2 identifies a system vulnerability that will allow a cyber attack to be successful. These two steps may occur simultaneously because a cyber attack is likely to attempt to exploit a system vulnerability to ensure success.

Step 3 of this process is the assessment of the effects of a successful cyber attack on a critical infrastructure control system. This step answers the question "How does the attack affect the control system and the components that are connected to the system?" Simulators that model control systems can be used to assess how the control system will react to the attack. This step can be informed by general heuristics, or rules-of-thumb, about the structure of the control systems to help inform the assessment.

During Step 4 of the process, the impact of the control system effects to the critical infrastructure being attacked (and possibly other, related infrastructure) is assessed. Infrastructure models are used to determine how the control system effects might spill over to other parts of the infrastructure that are not controlled by the attacked system. The result of this step is an infrastructure-impact scenario, which is a specific scenario of how the infrastructure is affected by the cyber attack. The scenario should specify the particular components of the infrastructure that are affected, as well as the details (time, severity, etc.) of the impacts.

Finally, during Step 5 of the process, the economic consequences of the infrastructure disruptions are found using the infrastructure-impact scenario. If the infrastructure-impact scenario constructed in Step 4 finds that the cyber attack may create disruptions in infrastructure, there will likely be economic ramifications to the loss. Economic models are available that can be used to assess the economic consequences of infrastructure disruptions caused by cyber attacks.

Process Walk-Through with Electric Power

This part of the case study explains Sandia's walk-through of the cyber-attack-consequence assessment process, using electric power as an example. Sandia's existing capabilities make this process relatively straightforward to accomplish for electric power.

Sandia has developed extensive capabilities for simulating electric power control systems through its participation in the National SCADA Test Bed (NSTB). NSTB is a multinational laboratory facility created by the U.S. Department of Energy's Office of Electricity Delivery and Energy Reliability (DOE-OE). A mission of NSTB is "identify[ing] and correct[ing] critical security flaws in SCADA control systems and equipment." Facilities are concentrated at the Center for Control System Security at Sandia and the Critical Infrastructure Test Range at Idaho National Laboratory.

The NSTB was created "to assist the energy sector and equipment vendors in improving the security of control systems hardware and software" and "has closely aligned its activities with industry-defined priorities. This part of the case study will also discuss how the capabilities that the NSTB has developed to model the effects of cyber attacks on physical assets, can be extended to explore how physical disruptions may cascade across infrastructures and assess the economic consequences of those disruptions.

Cyber-Attack and System-Vulnerability Steps

In the first two steps of the process, a cyber attack is identified along with the vulnerabilities in the control system that it may exploit. Because the Sandia report is most concerned with creating a roadmap for the final three steps of the process, it is assumed that these steps have been completed, and the results are available to inform the remaining steps of the process.

An example of results that may come from this step for an attack on electric power control systems is given in a scenario. In the scenario, multiple malevolent front-end processors (FEPs) have been compromised at the manufacturer or through software updates. An FEP is a computer that provides a bridge between client computers of human operators and power system hardware clients such as remote terminal units (RTUs). The FEP passes commands from the users to the hardware and provides the user with data from the power system hardware. The rogue FEPs are programmed to send breaker trip commands to generators, in order to induce widespread under-frequency load shedding during periods where power reserves are low (Stage 2 alerts), thus causing blackouts.

System Effect

Step 3 of the process assesses the effects of the cyber attack on the control systems being attacked. This step

can be informed by heuristics about infrastructure interdependencies that may facilitate the cyber attack. For example, if a utility's control systems were networked to computers that had Internet access, it would be possible that a cyber attack against that utility might affect the control systems, even if the attack was not directly aimed at those systems. Protected Critical Infrastructure Information (PCII) information collected from Department of Homeland Security (DHS) site-assist visits is a source of these data. These data are stored at Argonne National Laboratories.

The effects of cyber attacks against control systems can currently be assessed for electric power using the Virtual Control Systems Environment (VCSE), developed by Sandia as part of the NSTB program. The focus of VCSE modeling has been electric power control systems.

Infrastructure Impact

Cyber attacks can impact not only the entity that they attack, but other entities within the same infrastructure. These impacts can cascade into other infrastructures. The cumulative effect of these infrastructure disruptions will likely have an impact on the economy.

Disruptions in electric power are especially susceptible to spillovers. There are a limited number of alternating-current (AC) power grids in the contiguous United States. All components of each grid must operate in concert with one another, at the same frequency. Deviations in frequency or voltage may cause circuit breakers to open to protect equipment, which may further exacerbate the deviations, thus leading to a cascade of failures.

The NSTB currently has capabilities for assessing the impacts of cyber attacks on the electric power grid. The VCSE has the ability to interface with external software that simulates infrastructure systems. For example, in the cyber attack scenario developed in the *National SCADA Test Bed Threat Development Team, Threat case scenario*, a steady-state, loadshedding model is used to simulate the effects on a power grid. The VCSE also has the capability to interface with other software that can simulate infrastructures beyond power.

In this walk-through, the result of the system-effect step, coupled with the results from the VCSE, can be used to construct an infrastructure impact scenario for the impacts of a cyber attack on electric power. This scenario can be augmented to include the impact on other infrastructure through the use of the Fast Analysis and Simulation Team (FAST) Analysis Infrastructure Tool (FAIT).

Economic Consequences

A cyber attack on a control system may have effects beyond those of the attacked infrastructure identified in the infrastructure-impact step of the process. Infrastructures are interdependent, which means that a failure in one component may spill over to other components of the same infrastructure as well as associated infrastructures and industries. This interdependence is clear in the electrical power industry because almost all industries require electrical power in some manner. Disruptions of infrastructure may also spill over to economies. Economic activity depends on the infrastructure. A sustained loss of electric power, for example, may cause economic activity to nearly stop.

The consequences of infrastructure disruptions are complicated and difficult or impossible to measure in many cases and may vary greatly in their consequences. An outage at a single generator during a period with adequate reserve capacity is unlikely to disrupt service. Spot prices might be affected by the outage, but there will likely be little change to overall economic activity. The consequences of an outage that results in unserved load are more difficult to measure. For a short load-shedding event, the economic consequences will likely be light because many short-term economic losses are recoverable. For example, consumer purchases can be delayed to another day or time, and interrupted manufacturers can draw on inventories that can be replenished over time. Many of the losses that do occur may be difficult to quantify. For example, short losses of power chemical plants sometimes cause the release of chemicals and have the potential to cause accidents.

In the case of electric power, smaller outages are likely to affect a small area and last a short time. Consequences of the power outage are likely to be relatively small and affect a small number of parties. Identification of the consequences will, therefore, be difficult. On the other hand, a large blackout that lasts a long time will have larger consequences that affect nearly all infrastructures and individuals. Consequences identification will be much easier because of the importance and ubiquity of electric power.

In the NSTB workshop, some informal methods of assessing the economic consequences of cyber attacks to electric power systems were developed using the scenario in the *NationalSCADA Test Bed Threat Development Team, Threat case scenario*. The purpose of the exercise was to estimate the consequences of a cyber attack on a single utility company, rather than estimating the economic effects to the entire economy. A low-fidelity proxy for the cost of lawsuits due to a day-long blackout to the utility's entire service territory was created by calculating all of the direct and indirect economic impacts in the service territory. In reality, the effects of a cyber attack are likely to be more complex in terms of the coverage and duration of the blackout. Furthermore, the economic impact of the blackout is unlikely to be a complete loss of

all economic activity, especially for short-duration blackouts. However, economic losses may propagate beyond the immediate service area.

Gaps in Capabilities

There are several limitations to the capabilities described in the walk-through of the cyber attack-consequence assessment process for electric power. These gaps can be closed using capabilities that currently exist or are under development at Sandia. Closing these gaps will often add complications to the process because the gap-closing tools are more complex than those used in the walk-through. Researchers will need to decide whether the improvements to the results of the process (the infrastructure impact scenario and the measurement of the economic consequences) are worth the costs of the increased complexity.

Use of Unrealistic Power Grids

The Institute of Electrical and Electronics Engineers Reliability Test System-96 (IEEE RTS-96) power grid model, which is currently used by the VCSE steady-state simulator, is not a representation of a true power grid. The IEEE RTS-96 specification is just one possible specification, and it is chosen so that it simulates most features that exist throughout power grids. However, this specification is not a realistic representation of any actual grid. The IEEE RTS-96 specification contains generators with a total generating capacity of 10,215 megawatts (MW), which is much smaller than actual power grids. For example, the load that was lost in the Northeast Blackout of 2003 was 22,984 MW in the state of New York, alone. As with the power grid test bed, there are no associated infrastructures or economies; therefore, it is difficult to create infrastructure-impact scenarios that can be used to map power system impacts to infrastructure and economic consequences. Rules-of-thumb for the costs of outages to customers can be developed, but these rules are not specific to any particular scenario and include only direct economic impacts.

Other electric power models, in use or being developed by the NSTB at Sandia, use IEEE RTS-96 or specifications that are even more limited than IEEE RTS-96. While these models are useful for conducting experiments to see how cyber attacks affect electric power control systems, it is difficult to construct infrastructure-impact scenarios. Thus the models in use create a barrier to accurate consequence assessments.

The use of true-to-life power grid models would allow improved infrastructure-impact scenarios that would rely less on researchers' intuition. The steady-state model applied to IEEE RTS-96 produces estimates of hypothetical loads loss. A researcher has to decide how that maps to real world loads. If the steady-state model were applied to a real power grid, the output of the infrastructure simulation would show which loads were really lost. These areas could be mapped to counties and inputted into Regional Economic Accounting (tool (REAcct)) with a minimal number of additional assumptions.

Models of Electric Power Grids are Limited

The VCSE steady-state electric power model used in the earlier walk-through does not model the dynamic behavior of the power system, which may suppress power grid behavior that may be targeted by cyber attacks. Sandia is presently developing dynamic power models; however, their complexity may pose a barrier to using them with large, complex models of power grids. While the VCSE steady-state model currently works with the IEEE RTS-96 power grid, two other steady-state power grid models (PowerWorld and the Interdependent Energy Infrastructure Simulation System) use models of real power grids.

Economic Models are Limited

The REAcct methodology, which was discussed in the earlier walk-through of the cyber-attack consequence assessment process, is coarse due to the use of limiting assumptions. First, REAcct assumes that economic activity is spatially evenly distributed across a county. For example, if a disruption covers 5 percent of the area of a county and disrupts 50 percent of economic activity, REAcct assumes that 2.5 percent of economic activity is disrupted. However, if the county is sparsely populated, most economic activity could fall within the 5 percent of the county that receives the disruption. In this case, the parameters used by REAcct as inputs should be adjusted to reflect the uneven distribution of economic activity.

Second, REAcct calculates losses in gross regional product and income by assuming that all workers across the country have the same productivity. Data on county employment per industry are multiplied by average national productivity to generate estimates of gross regional product in each county. Because worker productivity varies by county, these estimates contain a degree of inaccuracy.

Third, the REAcct methodology is only valid for interruptions that last from about a week to a month. Depending on the nature of the disrupted asset, only some economic activity in an affected area may be lost. For example, a temporary power outage would not significantly affect businesses that had sufficient backup generation, nor would it significantly impact manufacturers who

can continue to meet demand with on-site or in-transit inventories.

Finally, REAcct assumes little about how the economy will adjust structurally to the disruption which may change the multiplier effects. For example, firms outside the disrupted area may pick up the slack in supply caused by the disruption, former suppliers to the disrupted firms may find new customers, and workers in the disrupted areas may move to find employment. More sophisticated economic models and tools which capture many of these long-term adjustment effects, such as the Regional Economics Models, Inc. (REMI), model, are more appropriate than REAcct for assessing long-term economic consequences that involve structural adjustments.

Extension of The Cyber-Attack-Consequence Assessment Process to other Infrastructures

As previously mentioned, this case study focuses on Sandia's capabilities in carrying out the cyber-attack-consequence assessment process using electric power control systems as an example. The process can be used with other critical infrastructure control systems with modifications to existing capabilities and the addition of infrastructure-impact simulations for new infrastructures.

Of the three steps of the cyber-attack-consequence assessment process focused upon in this case study, the systems-effects step and the infrastructure-impact step need to be modified from the electric power walk-through. For the final step (economic consequence assessment), the REAcct tool can continue to use the same type of infrastructure-disruption scenario as an input (specifications of which counties are affected, how long the disruption lasts, what fraction of their area is affected, and what fraction of economic activity is disrupted), provided that the necessary mappings of infrastructure disruptions to economic disruptions are made. Many of the economic assessment tools that filled the gaps of REAcct are similarly flexible or can include new infrastructures by expanding their models.

System Effect

The process walk-through detailed methods and tools that can currently be used to simulate a cyber attack on an electric power control system and assess the impacts to the electric power grid. Although these tools are tailored to the electric power industry, some tools, such as the VCSE, can be modified to different infrastructures. Other types of physical infrastructure can be simulated by either interfacing existing tools with the VCSE or creating new tools.

Infrastructure Impact

The infrastructure-impact step of the process maps changes in critical infrastructure control systems that are caused by cyber attacks to overall changes in infrastructure. The tools necessary to assess the infrastructure impact of cyber attacks will vary depending on the infrastructure being simulated, especially for infrastructures that have complex interdependencies among components. Thus, models of the specific infrastructure will be useful for developing a detailed and reliable infrastructure-impact scenario that shows how cyber attacks against a control system affect an infrastructure.

Economic Consequence

As mentioned earlier, the economic consequence tools are very flexible and can accommodate a variety of infrastructures, provided that the infrastructure-impact scenario can be mapped to a specific economic disruption. This mapping may be more difficult in infrastructures other than electric power. Most economic activity is highly dependent on electric power, but the same cannot be said for many other infrastructures. For example, a cyber attack on water treatment that resulted in a boil order would likely be more of an inconvenience than an event that halts all economic activity. In the extreme case of an infrastructure impact scenario where all water service was disrupted for a municipality, all economic activity would not be halted; much economic activity does not require water, and there are many common, alternative ways of obtaining water (such as wells).

More detailed economic consequence models, such as the National Infrastructure Simulation and Analysis Center (NISAC-Agent-Based Laboratory for Economics (N-ABLE™)), may be able to better model infrastructure disruptions that lead to more subtle economic disruptions than do interruptions in electric power. Heuristics can be used (or developed) to aid REAcct in mapping an infrastructure disruption to an economic disruption.

6. SOLUTION

The walk-through of the cyber-attack-consequence assessment process earlier in the case study, showed how the process can be easily applied to electric power. There was also an explanation of how some of the gaps in the process for electric power can be closed. Now, let's look at how the two extensions can better integrate the different steps of the process.

The first extension uses probabilistic modeling, which is currently being used for reliability analysis of electric power, to assess economic consequences. The second extension more fully integrates the final three steps of the

process at the software level by interfacing various tools so that the process can be conducted more efficiently.

Probabilistic Modeling

Critical infrastructures consist of complex engineering systems with many components. All of these components can fail, but the failure of individual components does not necessarily mean that the entire system will fail. A system, or parts of the system, is more likely to fail completely when multiple components fail at once.

Probabilistic analysis using the Monte Carlo simulation (An analytical technique in which a large number of simulations are run using random quantities for uncertain variables and looking at the distribution of results to infer which values are most likely. The name comes from the city of Monte Carlo (country of Monaco)), which is known for its casinos.) is often used in reliability engineering to assess the reliability of the system. The most basic simulation assumes that all components fail at random independently of one another. The failure of individual components of a system, can be simulated by assuming a probability distribution for the failure of that component, and drawing random numbers to determine whether the component has failed. For example, the exponential distribution is assumed if it is believed that a component has an equal chance of failing at any given time. Thus, failure of a component could be simulated when a randomly drawn number was below a given threshold during a specific period.

The exponential distribution has one parameter that must be specified for each component. The mean time to failure (MTTF) is, on average, how long a component will operate until it fails. If the recovery time of a component is also assumed to follow the exponential distribution, then another parameter (the mean time to recovery (MTTR)) must also be specified.

At each step, the state of the system is recalculated to reflect failures of individual components. Metrics about the state of the system are recorded. For example, in an electric power grid, the state of a bus (whether or not it is receiving power) could be recorded. After simulating the system for a long time, the recorded metrics can be analyzed to determine overall reliability. Because the Monte Carlo simulation operates over a long time, the results are most useful for determining the long-term costs of failures in the system.

Full Integration of Process Steps/Tools

Finally, a long-term goal may be to fully integrate the system-effect, infrastructure-impact, and economic-consequence steps of the process. Full integration might consist of a single user interface to conduct all three steps simultaneously, by using tools that are interfaced.

The system-effect and infrastructure-impact steps of the process are already interfaced for electric power by using the VCSE. The VCSE simulates the control system, but also interfaces to electric power grid models, which allows it to assess how a cyber attack affects control systems and how those effects propagate throughout the electric power grid. Furthermore, implementation of probabilistic analysis for economic consequences would likely require the infrastructure-impact and economic-consequence steps to be formally integrated so that the Monte Carlo analysis could run quickly.

7. CASE STUDY 3: DEPARTMENT OF HOMELAND SECURITY BATTLE INSIDER THREATS AND MAINTAIN NATIONAL CYBER SECURITY

The U.S. Department of Homeland Security (DHS) is a cabinet department of the U.S. federal government. Founded in 2003, the DHS was created in response to the horrific attacks of September 11th. Its mission is to secure the nation, protect it from terrorist attacks and respond to natural disasters. Headquartered in Washington, D.C., the DHS employs more than 340,000 people who are dedicated to keeping the nation safe. It is the third largest cabinet department, after the Department of Defense and Veterans Affairs, and it has a geographically dispersed network with 21 component agencies.

8. CHALLENGES

The DHS has a vital mission: to secure the nation. At the core of this mission, it was critical that DHS first improve and secure its own infrastructure that supports 21 geographically dispersed component agencies. In 2009, the DHS' Office of the Chief Information Officer, Information Technology Services Office and Risk Management Control Division were faced with the challenge of unifying the 21 component agencies. Their challenge was to strengthen the components through the creation of one secure network and reduce the number of data centers. In order to do this, the DHS needed to coordinate centralized, integrated activities across components that are distinct in their missions and operations. With scores of administrators accessing key critical national infrastructure at these core data centers, the DHS' Risk Management Control Division was tasked with ensuring contained access and monitoring, logging and tracking all administrative changes to its systems. In addition to stringent security policies, the DHS is subject to compliance regulations including Federal Desktop Core Configuration

(FDCC) standards. Launched by the Office of Management and Budget in 2007, the FDCC ensures that federal workstations have standardized, uniform, desktop configurations to enable more consistent and better documented security while reducing costs. The DHS needed a solution that would allow it to support the component consolidation effort, transforming the 21 sites by unifying and controlling access to key servers at those sites while maintaining the separation of duties within and across the component agencies. It also needed a solution that could quickly and easily be dropped into technology already in place. This was a challenging task because the DHS has a wide range of platforms and operating systems, including mainframes, UNIX, LINUX and Microsoft Windows.

9. SOLUTION

The solution criteria were crystal clear. The DHS needed a solution that supported remote access, desktop virtualization, two-factor authentication and auditing. It also needed out-of-the-box multi-platform support along with integration with existing cyber security products. As part of the selection process, the DHS vetted several cyber security products from a variety of market leading vendors. The DHS selected a cyber security product that provides access control for privileged users, including company employees, partners, consultants and IT staff, along with the computing infrastructure. The cyber security product controls, contains and audits the activity of privileged users, whether they originate from inside or outside of the network. The cyber security product also enforces fine grained access control policy on users, contains them to authorized systems and applications, and monitors, logs, records and reports their activities for compliance and security risk management. This gives DHS control over its privileged users and high risk assets. It also allows DHS to enforce access control policies and contains users in a manner that enables them to see only the network resources to which they have access. With an identity-based access control solution, the cyber security product provides the DHS with access control, user containment and audit-quality logging in a single appliance-based offering. From an operations and risk perspective, this allows the DHS to granularly control who gets access to what servers, when and for how long in an easy-to-manage unified offering. The cyber security product also enables DHS to contain users from its 21 sites to authorized systems and applications without any reconfiguration of its network. The cyber security product's capabilities also addressed the DHS requirement to maintain end-to-end accountability.

Finally, the cyber security product has increased security awareness at the DHS. With the cyber security product, the DHS has been able to provide privileged users with highly secure access to key servers in its facilities. As a result, the DHS has increased network security while enforcing the cyber security policy. The DHS has used the cyber security product to maintain Federal Desktop Core Configuration (FDCC) compliance. It does this at the desktop level since the secure access is provisioned via a Web browser without an additional desktop client required. The DHS has also used the cyber security product to streamline operations. This has been possible because the cyber security product provides a single solution for controlling, monitoring, logging and tracking all administrator changes. Now, DHS can easily determine when a change was made and the implications of that change. The DHS derived several additional benefits from the appliance. First, DHS found the anti-leapfrogging capabilities beneficial, which contain users to authorized resources. Another benefit was being able to add keystroke loggers to administrative accounts and prevent them from doing any intentional or unintentional damage.

10. CASE STUDY 4: CYBER SECURITY DEVELOPMENT LIFECYCLE

An employee was about to head home for the weekend from a utility company. Then the company‘s senior applications system analyst (and go-to computer programmer) heard from site administrators that something was odd with the utility‘s website. The programmer logged in to the code that controlled the troubled area and found himself staring not at the carefully engineered software he and those in his group helped create, but at a long string of seemingly random numbers and letters. Well, he thought, this can‘t be good. A quick Web search suggested that the utility‘s website application software was under attack from something called a botnet, a program built specifically to replicate malicious software on the Web. This particular botnet had an odd name: fringe47. It was spreading rapidly online by injecting itself into vulnerable websites and then waiting for unsuspecting users to click on the site. When they did, the code copied itself on their computers. In a few months, 360,000 sites had been infected. The programmer, who was careful to make sure his own machine wasn‘t infected as he researched fringe47, eventually found a safe security industry site that gave him enough details about the attack to alert one of his colleagues (manager of information protection at the company) that something was seriously wrong. Word then spread to others on the utility's IT team. Specifically, the code intended to take advantage of a weakness in a database method used to communicate called Structured Query Language, or SQL (pronounced −sequel‖). Fringe47 was diabolically engineered to sniff

out the Achilles heel in SQL. The botnet co-opted an application on the company Website and injected itself directly into a company database. The fear was that in the process, it could get past the utility‘s larger security perimeter and have its way with the company‘s software portfolio of applications, database tools and other code. It also had the potential to install itself on the computers of anyone who visited the utility‘s website. The attack was a legitimate risk to the utility. The immediate question was, could the company‘s highly sensitive information and processes (including customer billing data and energy trades) be compromised? Just 15 minutes after the programmer‘s first indication of the cyber attack, the utility had taken down the infected area, a section of the Website that contained news releases and other public relations information.

11. CHALLENGES

SQL injection attacks on corporate software applications are common — and, for victimized companies, the effects range from embarrassment to significant financial losses. Yet at first blush, the cyber attack on the utility seemed fairly innocuous. Fringe47 didn‘t appear to be causing damage, but it was replicating. The code was not meant to *steal information* from the utility. It was used to *spread the code* to those who came to the website.

The utility did the right thing: To avoid infecting Website users‘ computers, the company took down the infected pages. Once it did so, the IT staff started dissecting the cyber attack. The programmer and his colleagues identified two internal flaws that had repercussions throughout the utility‘s software architecture: data validation and improper rights administration.

Data Validation

When visitors came to utility.com looking for a press release, they would input a date to find the document they wanted. As long as they typed in an actual date, everything worked fine. But fringe47 exploited a flaw: Instead of a day, month and year, it inserted a long string of what appeared to be random letters, numbers, and characters. The string was anything but random, however. Because the Website code wasn‘t designed to validate that the data entered was in a true 8-digit date format, this long, alphanumeric code replaced the original data on the company database with a nefarious computer program.

Improper Rights Administration

Because of the way the site‘s Web application was originally coded, the requests for press releases were given the right not only to read from (but to write to) the company database. Fringe47 took advantage of these loose privileges to gain access to a part of the utility‘s information infrastructure. As obvious as this vulnerability sounds now, that wasn‘t the case when the code was written more than a decade ago. Back then, Web-based attacks were a rarity and the utility had never felt threatened. But, by not updating its application software as cyber criminals got more sophisticated, the company exposed itself to a new generation of risk.

Give Me a Break

In retrospect, the utility got two lucky breaks: First, the original program between the computer that held company data and the one that handled the Web page was set up to limit the time the two could communicate. This so-called, break‖ design, a throwback to the days when data service was slow and expensive, minimized the server‘s data load. As a result, fringe47 could compromise only the first few rows of the core SQL database before it was cut off. That limited the damage. Second, the utility‘s corporate communications staff made a habit of going through online press releases once a month to make sure the links still worked. This monthly audit found one that didn‘t, prompting a call to the IT service desk at the utility, which contacted Website administrators, who tipped off the programmer that something was amiss. As seemingly benign as the cyber attack initially appeared, the utility knew that whoever was behind it was savvy enough to know how to get inside a company – deep inside.

Deja Vu All Over Again

A few months later, an identical cyber attack hit the utility’s Website again. The utility had been warned about the vulnerabilities and fixed the vast majority of risks – except for one on a single, long-forgotten page. That was just enough to facilitate a fresh cyber assault. The utility had been stung by yet another outmoded cyber security practice: relying on a checklist approach to security. Prior to the cyber security overhaul, the company started with the traditional process for designing a software product: create lists of what the software would do, lay out how the software would do those tasks, set specific goals for design and other features, and start testing and debugging on the way to a release date.

The company initially took the same approach to dealing with the SQL attack. Once the utility had been flagged about the fringe47 injection, its developers made a list of all potential places they might be exposed, and closed weaknesses one at a time. But they missed one.

It was one single, old Web page that had not been touched in years. But, that second fringe47 attack gave

the utility another clue: The cyber attacker had used a specific type of Google search to pinpoint vulnerabilities with lethal accuracy. Dubbed Google Hacking, by security pros, the technique uses Google's powerful search engine to ferret out weaknesses in Web-based software. This strategy hides the cyber attack from most targets, to the point where Google Hacking victims typically have no clue they're being targeted.

The utility thought it was protected, but it failed to heed one sign: A few years earlier, several third-party security auditors warned the company it was vulnerable to SQL injection attacks. There was some skepticism about the exploitability of these threats. The utility had attempted to secure its applications once before. Seven years earlier, the company started working to improve how it developed new software. But, the commitment to go back in and fix older code was beyond that effort.

Hackers are Way Beyond Smart

Hackers continue to find new avenues of attack. A relatively small group of developers, already extremely busy, now had to find time to find and fix an unknown number of cyber security risks over a vast critical IT infrastructure that supported not only the company website, but every business unit in the company: services like customer care and human resources; applications that run the business like energy trading; and, even how the utility generates and distributes power.

12. SOLUTION

The utility knew it wanted (needed) a new culture for how it engineered, developed and tested its software. It also knew it wanted that culture grounded in widely accepted standards. That way, coders could learn from one another, and the company would not be re-inventing its cultural wheel to make its software more secure. The catch was, no one on staff knew much about how to make applications safer.

The design phase of the cyber security development lifecycle (CSDL) requires developers to create something called a cyber threat model. That is, a sense of the cyber attacks an application *might* face. What kind of exploits might a cyber attacker use? How would hackers gain access to an application running on a computer network? What older, existing pieces of code associated with the new application might be vulnerable? This overall feel for the risks an application might come under allows coders to *anticipate* risks. Threat models need not be complex: Even high-quality ones can be done on the back of cocktail napkins.

Once the standard was set, critical areas were addressed and basic training was completed, next up was spreading the new cyber security culture inside the utility. Two basic lines of work emerged: remediation on the existing code where needed, and maximizing the cyber security of all new code created from that point on. The company-wide remediation was a copy of the early, high-level work on the website: carefully anticipating threats identified by the utility's version of CSDL, analyzing each threat and then refactoring code where necessary. This strategic work was buttressed by scanning tools that helped identify high, medium and low risks. But, despite this automatic assistance, it was immediately clear the work ahead would not be easy.

Time was something the utility's coders had little of. Its IT department was designed to be an internal resource for the coding needs of various departments: providing the company's energy traders with a new way to manage their inventory, helping human resources manage employee benefits, and planning how utilities route their electricity or gas. But, under a mandate from the top, they found a way. And, slowly, cyber software security at the utility moved from afterthought to top-of-mind. Under CSDL, the utility now *started* with cyber security. Step one in the process was identifying a well-thought-out set of cyber threats that showed where a piece of software might be weak. How would the code be used? What was at risk? Then, using its new test tools and protocols, the entire development team became responsible for keeping the code within the standard. The utility had even gone so far as to install a last step — a human review to triple check that all new code cleared the cyber security bar before it went live.

But, the preceding only shows a small piece of what the utility achieved. The company learned that cyber security is *not* an absolute. It is the natural extension of an overall approach to keeping its informational ecosystem immune to cyber attack. Today, the company views cyber security as an evolving issue that forces it to stay ahead of new threats. That means considering cyber security from day one and abandoning a culture of pushing out code as fast as possible.

13. CASE STUDY 5: CYBER SECURITY AND BEYOND . . .. . .

Cyber security is an essential tool for managing risks in today's increasingly dynamic and capable cyber threat landscape. Yet the market for cyber security remains small, and organizations are making only tactical investments in cyber security measures—one of the reasons why there has been an increase in cyber attacks. Evidence suggests that this trend will last for some time to come. However, the anticipation of an increasingly open and mobile enterprise should help refocus the

spotlight on strategic investments in areas like cyber security. Cyber security professionals who wish to see cyber security move up in IT's priority queue should take immediate steps such as demanding secure software from suppliers and requiring rigorous acceptance tests for third-party code to help promote cyber security in the long run.

Because cyber security has a significant impact on vulnerability management, one could infer that the spotlight is only shifting to a different perspective and that commitment to cyber security may not have declined in the final analysis. Although viewed as a priority by many cyber security professionals, cyber security has not seen the appropriate commitment level reflected in IT's budget allocation.

For example, data breaches resulting from web application hacking are almost always accomplished through the exploitation of application vulnerabilities like SQL injection or cross-site scripting. If cyber security is not improved at a larger scale, the industry will continue to be plagued with security incidents that result in data breaches or other consequences that are even more disastrous. Changing the attitude toward cyber security, however, would require a culture shift, a shift that places importance on proactive risk management rather than immediate ROI. This shift won't happen overnight. In the meantime, cyber security professionals should follow these recommendations to implement a few immediate measures to effect positive changes:

- Demand software quality and security from suppliers.
- Perform stringent acceptance tests for third-party code.
- Disable default accounts from applications.
- Establish a secure operational environment for applications.
- Implement effective bug-reporting and handling.

14. CHALLENGES

As the buyer side starts to demand secure cyber software, the power balance will start to shift toward more strategic approaches to managing cyber-level risks. Cyber security professionals can encourage this change by engaging in these longer-term initiatives:

- Work toward an industry certification program for secure development practices.
- Implement a cyber security program.
- Continue to drive awareness of the changing cyber threat landscape.

So, in order to improve cyber security, companies and cyber security professionals should work in a concerted fashion to cultivate a culture that values and promotes cyber security. To help usher in such a culture, cyber security professionals should:

- Do their part to promote a cyber security ecosystem.
- Use mobile proliferation as a catalyst for cyber security.

And Beyond ....

Now, let's take quick preview of what cyber security will have to deal with in the near future. Recently, McAfee unearthed a massive, global cyberattack campaign named "Operation Shady RAT" that compromised more than 70 major organizations. Here's what you need to know.

So Where Was DHS When "Operation Shady Rat" Was Alive and Well During the Last 8 Years??

Cybercriminals from China have spent more than six years cautiously working to obtain data from more than 70 government agencies, corporations and non-profit groups. The campaign, named Operation Shady RAT (remote access tool) was discovered by the security firm McAfee.

While most of the targets have removed the malware, the operation persists. The good news: McAfee gained access to a command-and-control server used by the cyber attackers and has been watching, silently. U.S. law enforcement officials are working to shut down the operation. The Chinese government is denying that it sanctioned the cyber attack operation; although, configuration plans for the new DoD F-35 stealth figher were comprised by the cyber attackers. So, with the preceding in mind, the following are five things that came to light:

- Seventy-two (72) organizations were compromised.
- It was just not North America and Europe.
- When the coast was determined to be clear, the cyber attackers struck.
- This was a single operation by a single group (probably the Chinese).
- The only organizations that are exempt from this cyber threat were those that didn't have anything valuable or interesting worth stealing, from a national security point of view.

The loss of this data represents a massive economic cyber threat not just to individual companies and industries, but to entire countries that face the prospect of decreased economic growth in a suddenly more competitive landscape; the loss of jobs in industries that lose out to unscrupulous competitors in another part of the world; not to mention, the national security impact of the loss of sensitive intelligence or defense information.

Yet, the public (and often the industry) understanding of this significant national cyber security threat is largely minimal due to the very limited number of voluntary disclosures by victims of intrusion activity compared to the actual number of compromises that take place. With the goal of raising the level of public awareness today, this is not a new cyber attack, and the vast majority of the victims have long since remediated these specific infections. Although, whether most victims realized the seriousness of the intrusion or simply cleaned up the infected machine without further analysis into the data loss remains an open question.

The actual intrusion activity may have begun well before 2006, but that is the earliest evidence that was found for the start of the compromises. The compromises themselves were standard procedure for these types of targeted intrusions: a spear-phishing email containing an exploit is sent to an individual with the right level of access at the company, and the exploit when opened on an unpatched system will trigger a download of the implant malware. That malware will execute and initiate a backdoor communication channel to the web server and interpret the instructions encoded in the hidden comments embedded in the webpage code. This will be quickly followed by live intruders jumping on to the infected machine and proceeding to quickly escalate privileges and move laterally within the organization to establish new persistent footholds via additional compromised machines running implant malware; as well as, targeting for quick exfiltration the key data that the cyber attackers came for. In the end, one very critical question remains unanswered: Why wasn't the Department of Homeland Security (DHS) all over this cyber breach during the last 6 years when "Operation Shady Rat" was alive and well?? After all, isn't DHS supposed to be the security guardians of the cyber world?

If "Operation Shady Rat," wasn't bad enough, hackers are now using outfitted model planes/drones to hack into your wireless system. Built from an old Air Force target drone, the Wireless Aerial Surveillance Platform (WASP) packs a lot of technological power into a flying high-end cyber endurance package.

Could it Get any Worse: Use of Model Planes/ Drones to Hack into Wireless Systems

Built with a tiny on-board computer (Linux powered, natch), the WASP is bristling with hacking tools, along with a custom-built 340 million word dictionary for brute-forcing passwords, the BackTrack suite (BackTrack provides users with easy access to a comprehensive and large collection of security-related tools ranging from port scanners to password crackers.), a 4 G T-Mobile card, an HD camera, and 32 GB onboard storage. Just what does WASP do with those gigabytes? Originally, it was designed for Wi-Fi penetration — cracking network passwords while loitering above a target area. But, the newly upgraded WASP can now trick GSM phones into connecting with its 4 G card as if it were a standard cellphone tower. Once connected, the WASP quietly records any phone conversations or text messages while connecting the call via VOIP, thus giving the mark the impression that the call went through normally.

Keep in mind that nothing on the WASP is particularly new. The password cracking techniques have been around for quite some time, and the phone-spoof is based off a trick shown off at Defcon in 2010. But, by placing them on a flying platform, consumer technology and hacking techniques have progressed to the point where once untouchable targets are now vulnerable.

If "Operation Shady Rat," and "WASP" weren't bad enough, hackers are now targeting security companies. Recently, a band of Internet vigilantes calling itself Anonymous (17 of whom were recently arrested by FBI raids), had sneaked into several security companies' computers to demonstrate those companies' insecurity.

Worse and Worser: Cyber Security Guardians are Now Hacker Targets

Recently, several security firms and consultants have been hit by the cyber intruders they are hired to keep at bay. The group, calling itself Anonymous, released internal company documents from those security firms.

The security firms and consultants are hired to protect corporate and government data, including the most confidential intelligence information, across a vast virtual frontier. The string of embarrassing cyber attacks on them demonstrates how vulnerable everyone is online, including those who are paid to be the protectors.

Other cyber attackers are mysterious and more worrying entities than the Anonymous group; as in the case of the still unknown organization (probably Chinese) that recently breached the systems of RSA, whose electronic security tokens are used across many industries. The cyber hackers used information obtained in the RSA cyber attack to break into Lockheed Martin, the largest military contractor in the country.

Anonymous, for its part, has made it plain that it goes after defense and intelligence contractors to expose their security vulnerabilities, not for financial or strategic gain. Booz Allen Hamilton, a company based in McLean, Va. (that does computer security work for the Defense Department), was also hit by the group. The cyber hackers released the e-mail addresses of over 100,000 military personnel.

The most notorious breach of a security company came after an executive at HBGary Federal, a relatively

small consultant eyeing a government contract, boasted publicly of his ability to unmask the members of Anonymous. In response, hackers made off with a large trove of the company's e-mail messages and dumped them online, exposing details of its business transactions.

The spate of cyber attacks (and the fear of more) could actually end up buoying the fortunes of the global cyber security industry. All of the major defense and intelligence contractors have expanded their digital cyber security wings in recent years. They are simply following the money.

For better or worse, securing the Internet has been largely left to private players. Even government information, is increasingly guarded by private companies, whose actions can be difficult to monitor and hold accountable.

Finally, speaking of worse, the group known as Anonymous has struck again! Recently, the cyber hacker group hacked into some 80 mostly rural law enforcement websites in the United States, a data breach that leaked sensitive information about ongoing investigations. The cases have now been compromised, and may be thrown out.

Revenge of Anonymous

The loose-knit international cyber hacking collective known as Anonymous, posted a cache of data to the Internet, including emails stolen from officers, tips which appeared to come from members of the public, credit card numbers and other information. Anonymous claimed that it had stolen 20 gigabytes worth of data in retaliation for arrests of its sympathizers in the U.S. and Britain.

Though many of the leaked emails appeared benign, some of the stolen material carried sensitive information, including tips about suspected crimes, profiles of gang members and cyber security training. The emails were mainly from sheriffs' offices in Arkansas, Kansas, Louisiana, Missouri and Mississippi.

Anonymous did not specify why these sheriffs' departments were targeted. But, Anonymous members have increasingly been pursued by law enforcement in the United States and elsewhere following a string of high-profile data thefts and denial of service attacks — operations that block websites by flooding them with traffic.

Recently, the FBI and British and Dutch officials, made 32 arrests. Many of the arrests related to the group's attacks on Internet payment provider PayPal Inc., which has been targeted over its refusal to process donations to WikiLeaks. The group also claims credit for disrupting the websites of Visa and MasterCard, when the credit card companies stopped processing donations to WikiLeaks and its founder, Julian Assange.

Chapter e39

Public Key Infrastructure

Terence Spies
Voltage Security

The ability to create, manipulate, and share digital documents has created a host of new applications (email, word processing, e-commerce websites), but also created a new set of problems, namely how to protect the privacy and integrity of digital documents when stored and transmitted. The invention of public key cryptography in the 1970s [1] pointed the way to a solution to those problems, most importantly the ability to encrypt data without a shared key, and the ability to "sign" data, insuring its origin and integrity. While these operations are quite conceptually simple, they both rely on the ability to bind a public key (which is typically a large mathematical object) reliably with an identity sensible to the application using the operation (for example, a globally unique name, a legal identifier, or an email address.) Public Key Infrastructure (PKI) is the umbrella term used to refer to the protocols and machinery used to perform this binding.

The most important security protocols used on the Internet rely on PKI to bind names to keys – a crucial function that allows authentication of users and websites. A set of attacks in 2011 called into question the security of the PKI architecture [2,3], especially when governmental entities might be tempted to subvert Internet security assumptions. A number of interesting proposed evolutions of the PKI architecture have been proposed as potential countermeasures to these attacks. Even in the face of these attacks, PKI remains the most important and reliable method of authenticating networked entities.

1. CRYPTOGRAPHIC BACKGROUND

To understand how PKI systems function, it is necessary to grasp the basics of public key cryptography. PKI systems enable the use of public key cryptography, and they also use public key cryptography as the basis for their operation. While there are thousands of varieties of cryptographic algorithms, we can understand PKI operations by looking at only two: signature and encryption.

Digital Signatures

The most important cryptographic operation in PKI systems is the digital signature. If two parties are exchanging some digital document, it may be important to protect that data so that the recipient knows that the document has not been altered since it was sent, and that any document received was indeed created by the sender. Digital signatures provide these guarantees by creating a data item, typically attached to the document in question that is uniquely tied to the data and the sender. The recipient then has some verification operation that confirms that the signature data matches the sender and the document.

Figure e39.1 illustrates the basic security problem that motivates signatures. An attacker controlling communications between the sender and receiver can insert a bogus document, fooling the receiver.

The aim of the digital signature is to block this attack by attaching a signature that can only be created by the sender, as shown in Figure e39.2.

Cryptographic algorithms can be used to construct secure digital signatures. These techniques (for example, the RSA or DSA algorithms) all have the same three basic operations, as shown in Table e39.1.

Public Key Encryption

Variants of the three operations used to construct digital signatures can also be used to encrypt data. Encryption uses a public key to scramble data in such a way that only the holder of the corresponding private key can unscramble it (see Figure e39.3).

Public key encryption is accomplished with variants of the same three operations used to sign data, as shown in Table e39.2.

The security of signature and encryption operations depends on two factors: first, the ability to keep the private key private and, second, the ability to reliably tie a public key to a sender. If a private key is known to an attacker, they can then perform the signing operation on

TABLE e39.1 The Three Fundamental Digital Signature Operations.

Key Generation	Using some random source, the sender creates a public and private key, called Kpublic and Kprivate. Using Kpublic, it is cryptographically difficult to derive Kprivate. The sender then distributes Kpublic, and keeps Kprivate hidden.
Signing	Using a document and Kprivate, the sender generates the signature data.
Verification	Using the document, the signature, and Kpublic, the receiver (or any other entity with these elements) can test that the signature matches the document, and could only be produced with the Kprivate matching Kpublic.

arbitrary bogus documents, and can also decrypt any document encrypted with the matching public key. The same attacks can be performed if an attacker can convince a sender or receiver to use a bogus public key.

PKI systems are built to securely distribute public keys, thereby preventing attackers from inserting bogus public keys. They do not directly address the security of private keys, which are typically defended by measures at a particular endpoint, such as keeping the private key on a smartcard, encrypting private key data using operating system facilities, or other similar mechanisms. The remainder of this section will detail the design, implementation, and operation of public key distribution systems.

TABLE e39.2 The Three Fundamental Public Key Encryption Operations.

Key Generation	Using some random source, the sender creates a public and private key, called Kpublic and Kprivate. Using Kpublic, it is cryptographically difficult to derive Kprivate. The sender then distributes Kpublic, and keeps Kprivate hidden.
Encryption	Using a document and Kpublic, the sender encrypts the document.
Decryption	The receiver uses Kprivate to decrypt the document.

2. OVERVIEW OF PKI

PKI systems solve the problem of associating meaningful names with essentially meaningless cryptographic keys. For example, when encrypting an email, the user will typically specify a set of recipients that should be able to decrypt that mail. The user will want to specify these as some kind of name (email address or a name from a directory), not as a set of public keys. In the same way, when signed data is received and verified, the user will want to know what user signed the data, not what public key correctly verified the signature. The design goal of PKI systems is to securely and efficiently connect user identities to the public keys used to encrypt and verify data.

The original Diffie-Hellman paper [1] that outlined public key cryptography proposed that this binding would be done through storing public keys in a trusted directory. Whenever a user wanted to encrypt data to another user, they would consult the "public file" and request the public key corresponding to some user. The same operation would yield the public key needed to verify the signature on signed data. The disadvantage of this approach is that the directory must be online and available for every new encryption and verification operation. (While this older approach was never widely implemented, variants of this approach are now reappearing in newer PKI designs. For more information, see the section on Alternative PKI Architectures.)

PKI systems solve this online problem and accomplish identity binding by distributing "digital certificates", chunks of data that contain an identity and a key, all authenticated by digital signature, and providing a mechanism to validate these certificates. Certificates, first invented by Kohnfelder in 1978, are essentially a digitally signed message from some authority stating "Entity X is associated with public key Y." Communicating parties can then rely on this statement (to the extent they trust the authority signing the certificate) to use the public key Y to validate a signature from X or to send an encrypted message to X. Since time may pass between when the signed certificate is produced and when someone uses that certificate, it may be useful to have a validation mechanism to check that the authority still stands by certificate. We will describe PKI systems in terms of producing and validating certificates.

There are multiple standards that describe how certificates are formatted. The X.509 standard, promulgated by the ITU [4], is the most widely used, and is the certificate format used in the TLS/SSL protocols for secure Internet connections, and the S/MIME standards for secured email. The X.509 certificate format also implies a particular model of how certification works. Other standards have attempted to define alternate models of operation and associated certificate models. Among the other standards that describe certificates are: Pretty Good Privacy (PGP) [pgp], and the Simple Public Key Infrastructure

(SPKI) [spki]. In this section, we'll describe the X.509 PKI model, then describe how these other standards attempt to remediate problems with X.509.

3. THE X.509 MODEL

The X.509 model is the most prevalent standard for certificate based PKIs, though the standard has evolved such that PKI-using applications on the Internet are mostly based on the set of IETF standards that have evolved and extended the ideas in X.509. X.509 style certificates are the basis for SSL, TLS, many VPNs, the US Federal Government PKI, and many other widely deployed systems.

The History of X.509

A quick historical preface here is useful to explain some of the properties of X.509. X.509 is part of the X.500 directory standard owned by the International Telecommunications Union Telecommunications Standardization Sector (ITU-T). X.500 specifies a hierarchical directory useful for the X.400 set of messaging standards. As such, it includes naming system (called "distinguished naming") that describes entities by their position in some hierarchy. A sample X.500/X.400 name might look like this:

$$CN = \text{Joe Davis},\ OU = \text{Human Resources},\ O = \text{WidgetCo},\ C = \text{US}$$

This name describes a person with a Common Name (CN) of "Joe Davis" that works in an Organizational Unit (OU) called "Human Resources", in an Organization called "WidgetCo", in the United States. These name components were intended to be run by their own directory components (so, for example, there would be "Country" directories that would point to "Organizational" directories, etc.) and this hierarchical description was ultimately reflected in the design of the X.509 system. Many of the changes made by IETF and other bodies that have evolved the X509 standard were made to reconcile this hierarchical naming system with the more distributed nature of the Internet.

The X.509 Certificate Model

The X.509 model specifies a system of Certifying Authorities (CAs) that issue certificates for end entities (users, web sites, or other entities that hold private keys.) A CA issued certificate will contain (among other data) the name of the end entity, the name of the CA, the end entity's public key, a validity period, and a certificate serial number. All of this information is signed with the CA's private key. (Additional details on the information in a certificate and how it is encoded is in Section Z.) To validate a certificate, a relying party uses the CA's public key to verify the signature on the certificate, checks that the time falls within the validity period, and may also perform some other online checks.

This process leaves out on important detail: where did the CA's public key come from? The answer is that another certificate is typically used to certify the public key of the CA. This "chaining" action of validating a certificate by using the public key from another certificate can be performed any number of times, allowing for arbitrarily deep hierarchies of CAs. Of course, this must terminate at some point, typically at a self-signed certificate that is trusted by the relying party. Trusted self-signed certificates are typically referred to as "root" certificates. Once the relying party has verified the chain of signatures from the end-entity certificate to a trusted root certificate, it can conclude that the end-entity certificate is properly signed, and then move onto whatever other validation steps (proper key usage fields, validity dates in some time window, etc.) are required to fully trust the certificate. Figure e39.4 shows the structure of a typical certificate chain.

One other element is required for this system to function securely: CAs much be able "undo" a certification action. While a certificate binds an identity to a key, there are many events that may cause that binding to become invalid. For example, a CA operated by a bank may issue a certificate to a newly hired person that gives that user the ability to sign messages as an employee of the bank. If that person leaves the bank before the certificate expires, the bank needs some way of undoing that certification. The physical compromise of a private key is another circumstance that may require invalidating a certificate. This is accomplished by a validation protocol, where (in the abstract) a user examining a certificate can ask the CA if a certificate is still valid. In practice, revocation protocols are used that simulate this action without actually contacting the CA.

Root certificates are critical to the process of validating public keys through certificates. They must be inherently trusted by the application, since no other certificate signs these certificates. This is most commonly done by installing the certificates as part of the application that will use the certificates under a set of root certificates. For example, Internet Explorer uses X.509 certificates to validate keys used to make Secure Socket Layer (SSL) connections. Internet Explorer has a large set of root certificates installed which can be examined by opening the Internet Options menu item and selecting "Certificates" in the "Content" tab of the Options dialog. A list like the one in Figure e39.5 will appear:

This dialog can also be used to inspect these root certificates. The Microsoft Root certificate details look like the ones shown in Figure e39.6.

The meaning of these fields will be explored in subsequent sections.

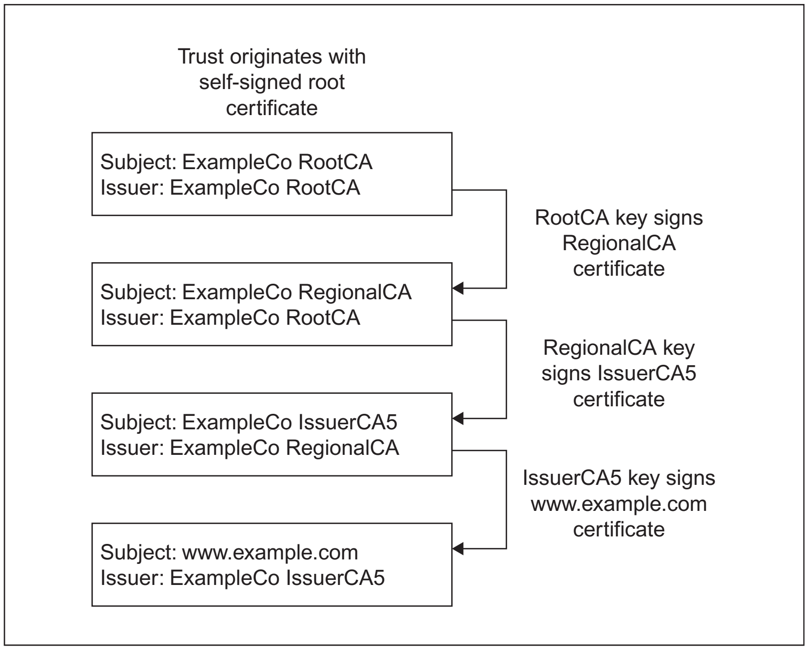

FIGURE e39.4 An example X.509 certificate chain.

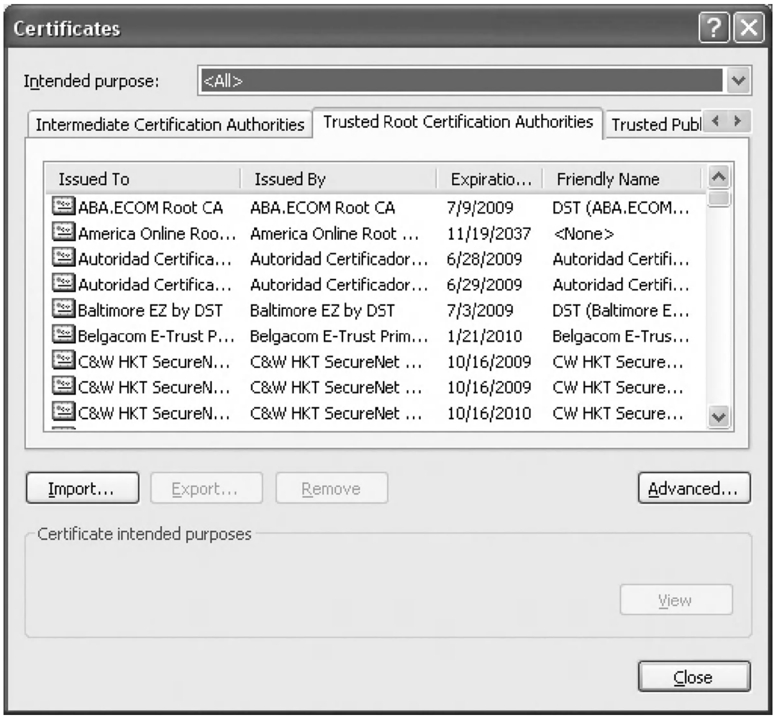

FIGURE e39.5 The Microsoft Internet Explorer trusted root certificates.

4. X.509 IMPLEMENTATION ARCHITECTURES

While, in theory, the Certification Authority is the entity that creates and validates certificates, in practice, it may be desirable or necessary to delegate the actions of user authentication and certificate validation to other servers. The security of the CA's signing key is crucial to the security of a PKI system. By limiting the functions of the server that holds that key, it should be subject to less risk of disclosure or illegitimate use. The X.509 architecture defines a delegated server role, the Registration Authority (RA), which allows delegation of authentication. Subsequent extensions to the core X.509 architecture

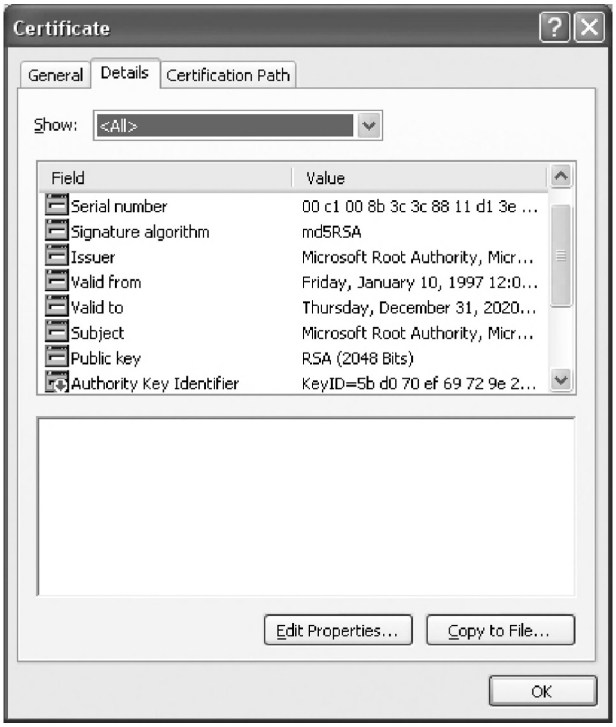

FIGURE e39.6 A view of the fields in an X.509 certificate using Microsoft Internet Explorer.

have created a second delegated role, the Validation Authority (VA), which owns answering queries about the validity of a certificate after creation.

A Registration Authority is typically used to distribute the authentication function needed to issue a certificate without needing to distribute the CA key. The RA's function is to perform the authentication needed to issue a certificate, then send a signed statement containing the fact that it performed the authentication, the identity to be certified, and the key to be certified. The CA validates the RA's message, and issues a certificate in response.

For example, a large multi-national corporation wants to deploy a PKI system using a centralized CA. It wants to issue certificates on the basis of in-person authentication, so needs some way to distribute authentication to multiple locations in different countries. Copying and distributing the CA signing key creates a number of risks, not only due to the fact that the CA key will be present on multiple servers, but also due to the complexities of creating and managing these copies. Sub-CAs could be created for each location, but this requires careful attention to controlling the identities allowed to be certified by each sub-CA (otherwise, an attacker compromising one sub CA could issue a certificate for any identity they liked.) One possible way to solve this problem is to create RAs at each location, and have the CA check that the RA is authorized to authenticate a particular employee when a certificate is requested. If an attacker subverts a given RA signing key, they can request certificates for employees in the purview of that RA, but it is straightforward, once discovered, to deauthorize the RA, solve the security problem, and create a new RA key.

Validation Authorities are given the ability to revoke certificates (the specific methods used to effect revocation are detailed in the X.509 Revocation Protocols section), and offload that function from the CA. Through judicious use of RAs and VAs, it is possible to construct certification architectures where the critical CA server is only accessible to a very small number of other servers, and network security controls can be used to reduce or eliminate threats from outside network entities.

5. X.509 CERTIFICATE VALIDATION

X.509 certificate validation is a complex process, and can be done to several levels of confidence. This section will outline a typical set of steps involved in validating a certificate, but is not an exhaustive catalog of the possible methods that can be used. Different applications will often require different validation techniques, depending on the application's security policy. It is rare for an application to implement certificate validation, as there are several APIs and libraries available to perform this task. Microsoft CryptoAPI, OpenSSL, and the Java JCE all provide certificate validation interfaces. The Server-based Certificate Validity Protocol (SCVP) can also be used to validate a certificate. However, all of these interfaces offer a variety of options, and understanding the validation process is essential to properly using these interfaces.

While a complete specification of the certificate validation process would require hundreds of pages, we supply a sketch of what happens during certificate validation. It is not a complete description, and is purposefully simplified. The certificate validation process typically proceeds in three steps, and typically takes three inputs. The first is the certificate to be validated, the second is any intermediate certificates acquired by the applications, and the third is a store containing the root and intermediate certificates trusted by the application. The following steps are a simplified outline of how certificates are typically validated. In practice, the introduction of bridge CAs and other non-hierarchical certification models have led to more complex validation procedures. IETF RFC 3280 [5] presents a complete specification for certificate validation, and RFC 4158 [6] presents a specification for constructing a certification path in environments where non-hierarchical certification structures are used.

Validation Step 1: Construct the Chain and Validate Signatures

The contents of the target certificate cannot be trusted until the signature on the certificate is validated, so the first step is to check the signature. To check the signature, the certificate for the authority that signed the target certificate must be located. This is done by searching the intermediate certificates and certificate store for a certificate with a Subject field that matches the Issuer field of the target certificate. If multiple certificates match, the validator can search the matching certificates for a Subject Key Identifier extension that matches the Issuer Key Identifier extension in the candidate certificates. If multiple certificates still match, the most recently issued candidate certificate can be used. (Note that, because of potentially revoked intermediate certificates, multiple chains may need to be constructed and examine through steps 2 and 3 to find the actual valid chain.) Once the proper authority certificate is found, the validator checks the signature on the target certificate using the public key in the authority certificate. If the signature check fails, the validation process can be stopped, and the target certificate deemed invalid.

If the signature matches, and the authority certificate is a trusted certficate, the constructed chain is then subjected to steps 2−4. If not, the authority certificate is treated as a target certificate, and Step 1 is called recursively until it returns a chain to a trusted certificate or fails.

Constructing the complete certificate path requires that the validator is in possession of all the certificates in that path. This requires that the validator keep a database of intermediate certificates or that the protocol using the certificate supplies the needed intermediates. The Server Certificate Validation Protocol (SCVP) provides a mechanism to request a certificate chain from a server, which can eliminate these requirements. The SCVP protocol is described in more detail in a subsequent section.

Step 2: Check Validity Dates, Policy and Key Usage

Once a chain has been constructed, various fields in the certificate are checked to insure that the certificate was issued correctly and that it is currently valid. The following checks should be run on the candidate chain:

The certificate chain times are correct. Each certificate in the chain contains a validity period with a not before and not after time. For applications outside validating the signature on a document, the current time must fall after the not before time and before the not after time. Some applications may require "time nesting", meaning that that the validity period for a certificate must fall entirely within the validity period of the issuer's certificate. It is up to the policy of the application if it treats out-of-date certificates as invalid, or treats it as a warning case that can be overridden by the user. Applications may also treat certificates that are not yet valid differently than certificates that have expired.

Applications that are validating the certificate on a stored document may have to treat validity time as the time that the document was signed as opposed to the time that the signature was checked. There are three cases of interest. The first, and easiest, is where the document signature is checked, and the certificate chain validating the public key contains certificates that are currently within their validity time interval. In this case, the validity times are all good, and verification can proceed. The second case is where the certificate chain validating the public key is currently invalid because one or more certificates are out-of-date, and the document is believed to be signed at a time when the chain was out-of-date. In this case, the validity times are all invalid, and the user should be at least warned.

The ambiguous case arises when the certificate chain is currently out-of-date, but the chain is believed to have been valid with respect to time when the document was signed. Depending on its policy, the application can treat this case in several different ways. It can assume that the certificate Validity times are strict, and fail to validate the document. Alternatively, it can assume that the certificates were good at the time of signing, and validate the document. The application can also take steps to insure that this case does not occur by using a time-stamping mechanism in conjunction with signing the document, or provide some mechanism for resigning documents before certificate chains expire.

Once the certificate chain has been constructed, the verifier must also verify that various X.509 extension fields are valid. Some common extensions that are relevant to the validity of a certificate path are:

- ***BasicConstraints***: This extension is required for CAs, and limits the depth of the certificate chain below a specific CA certificate.
- ***NameConstraints***: This extension limits the namespace of identities certified underneath the given CA certificate. This extension can be used to limit a specific CA to issuing certificates for a given domain or X.400 namespace.
- ***KeyUsage*** and ***ExtendedKeyUsage***: These extensions limit the purposes a certified key can be used for. CA certificates must have KeyUsage set to allow certificate signing. Various values of ExtendedKeyUsage may be required for some certification tasks.

Step 3: Consult Revocation Authorities

Once the verifier has concluded that it has a suitably signed certificate chain with valid dates and proper

keyUsage extensions, it may want to consult the revocation authorities named in each certificate to check that the certificates are currently valid. Certificates may contain extensions that point to Certificate Revocation List (CRL) storage locations or to Online Certificate Status Protocol (OSCP) responders. These methods allow the verifier to check that a CA has not revoked the certificate in question. The next section details these methods in more detail. Note that each certificate in the chain may need to be checked for revocation status. The next section on certificate revocation details the mechanisms used to revoke certificates.

6. X.509 CERTIFICATE REVOCATION

Since certificates are typically valid for a significant period of time, it is possible that during the validity period of the certificate, a key may be lost or stolen, an identity may change, or some other event may occur that causes a certificate's identity binding to become invalid or suspect. To deal with these events, it must be possible for a CA to revoke a certificate, typically by some kind of notification that can be consulted by applications examining the validity of a certificate. Two mechanisms are used to perform this task: Certificate Revocation Lists (CRLs) and the Online Certificate Status Protocol (OCSP)

The original X.509 architecture implemented revocation via a Certificate Revocation List (CRL.) A CRL is a periodically issued document containing a list of certificate serial numbers that are revoked by that CA. X.509 has defined two basic CRL formats, V1 and V2. When CA certificates are revoked by a higher-level CA, the serial number of the CA certificate is placed on an Authority Revocation List (ARL), which is formatted identically to a CRL. CRLs and ARLs, as defined in X.509 and IETF RFC 3280 are ASN.1 encoded objects that contain the following information shown in Table e39.3.

TABLE e39.3 Data Fields in an X.509 CRL.

Version	Specifies the format of the CRL. Current version is 2.
Signature Algorithm	Specifies the algorithm used to sign the CRL
Issuer	Name of the CA issuing the CRL
thisUpdate	Time from when this CRL is valid
nextUpdate	Time when the next CRL will be issued

This header is followed by a sequence of revoked certificate records. Each record contains the following information shown in Table e39.4.

TABLE e39.4 Format of a Revocation Record in an X.509 CRL.

Serial Number	Serial number of a revoked certificate
Revocation Date	Date the revocation is effective
CRL Extensions	[optional] specifies why the certificate is revoked

The list of revoked certificates is optionally followed by a set of CRL extensions that supply additional information about the CRL and how it should be processed. To process a CRL, the verifying party checks that the CRL has been signed with the key of the named issuer, and that the current date is between the thisUpdate time and the nextUpdate time. This time check is crucial, because if it is not performed, an attacker could use a revoked certificate by supplying an old CRL where the certificate had not yet appeared. Note that expired certificates are typically removed from the CRL, which prevents the CRL from growing unboundedly over time.

Note: CRLs can only revoke certificates on time boundaries determined by the nextUpdate time. If a CA publishes a CRL every Monday, for example, a certificate that is compromised on a Wednesday will continue to validate until it's serial number is published in the CRL on the following Monday. Clients validating certificates may have downloaded the CA's CRL on Monday, and are free to cache the CRL until the nextUpdate time occurs. This caching is important, as it means that the CRL is only downloaded once per client per publication period, rather than for every certificate validation. However, it has the unavoidable consequence of having a potential time-lag between a certificate becoming invalid and its appearance on a CRL. The online certificate validation protocols detailed in the next section attempt to solve this problem.

The costs of maintaining and transmitting CRLs to verifying parties has been repeatedly identified as an important component of the cost of running a PKI system [7,8], and several alternative revocation schemes have been proposed to lower this cost. The cost of CRL distribution was also a factor in the emergence of online certificate status checking protocols like OCSP and SCVP.

Delta CRLs

In large systems that issue many certificates, CRLs can potentially become quite lengthy. One approach to reducing the network overhead associated with sending the

complete CRL to every verifier is to issue a Delta CRL along with a Base CRL. The base CRL contains the complete set of revoked certificates up to some point in time, and the accompanying Delta CRL contains only the additional certificates added over some time period. Clients that are capable of processing the Delta CRL can then download the Base CRL less frequently, and download the smaller Delta CRL to get recently revoked certificates. Delta CRLs are formatted identically to CRLs, but have a critical extension added in the CRL that denotes that they are a Delta, not Base CRL. IETF RFC 3280 [5] details how Delta CRLs are formatted, and the set of certificate extensions that indicate that a CA issues Delta CRLs.

Online Certificate Status Protocol

The Online Certificate Status Protocol (OSCP) was designed with the goal of reducing the costs of CRL transmission, and eliminating the time-lag between certificate invalidity and certificate revocation inherent in CRL based designs. The idea behind OCSP is straightforward. A CA certificate contains a reference to an OSCP server. A client validating a certificate transmits the certificate serial number, a hash of the issuer name, and a hash of the subject name, to that OSCP server. The OSCP server checks the certificate status and returns an indication as to the current status of the certificate. This removes the need to download the entire list of revoked certificates, and also allows for essentially instantaneous revocation of invalid certificates. It has the design tradeoff of requiring that clients validating certificates have network connectivity to the required OCSP server.

OSCP responses contain the basic information as to the status of the certificate, in the set of "good", "revoked", or "unknown." They also contain a thisUpdate time, similarly to a CRL and are signed. Responses can also contain a nextUpdate time, which indicates how long the client can consider the OSCP response definitive. The reason the certificate was revoked can also be returned in the response. OSCP is defined in IETF RFC 2560 [9].

7. SERVER-BASED CERTIFICATE VALIDITY PROTOCOL

The X.509 certificate path construction and validation process requires a non-trivial amount of code, the ability to fetch and cache CRLs, and, in the case of mesh and bridge CAs, the ability to interpret CA policies. The Server-based Certificate Validity Protocol [10] was designed to reduce the cost of using X.509 certificates by allowing applications to delegate the task of certificate validation to an external server. SCVP offers two levels of functionality: Delegated Path Discovery (DPD), which attempts to locate and construct a complete certificate chain for a given certificate, and Delegated Path Validation (DPV), which performs a complete path validation, including revocation checking, on a certificate chain. The main reason for this division of functionality is that a client can use an untrusted SCVP server for DPD operations, since it will validate the resulting path itself. Only trusted SCVP servers can be used for DPV, since the client must trust the server's assessment of a certificate's validity.

SCVP also allows checking certificates according to some defined certification policy. The can be used to centralize policy management for an organization that wishes all clients to follow some set of rules with respect to what set of CAs are trusted, what certification policies are trusted, etc. To use SCVP, the client sends a query to an SCVP server, which contains the following parameters:

- ***QueriedCerts***. This is the set of certificates that the client wants the server to construct (and optionally validate) paths for.
- ***Checks***. The Checks parameter specifies what the client wants the server to do. The checks parameter can be used to specify that the server should build a path, should build a path and validate it without checking revocation, or should build and fully validate the path.
- ***WantBack***. The WantBack parameter specifies what the server should return from the request. This can range from the public key from the validated certificate path (in which case the client is fully delegating certificate validation to the server), to all certificate chains that the server can locate.
- ***ValidationPolicy***. The ValidationPolicy parameter instructs the server how to validate the resultant certification chain. This parameter can be as simple as "use the default RFC 3280 validation algorithm" or can specify a wide range of conditions that must be satisfied. Some of the conditions that can be specified with this parameter are:
    - ***KeyUsage and Extended Key Usage***. The client can specify a set of KeyUsage or ExtendedKeyUsage fields that must be present in the end-entity certificate. This allows the client to only accept, for example, certificates that are allowed to perform digital signatures.
    - ***UserPolicySet***. The client can specify a set of certification policy OIDs that must be present in the CAs used to construct the chain. CAs can assert that they follow some formally defined policy when issuing certificates, and this parameter allows the client to only accept certificates issued under some set of these policies. For example, if a client wanted to only accept certificates acceptable under the Medium Assurance Federal Bridge CA

policies, it could assert that policy identifier in this parameter. For more information on policy identifiers, see the section on X.509 Extensions.

- ***InhibitPolicyMapping***. When issuing bridge or cross-certificates, a CA can assert that a certificate policy identifier in one domain is equivalent to some other policy identifier within it's domain. By using this parameter, the client can state that it does not want to allow these policy equivalences to be used when validating certificates against values in the UserPolicySet parameter.
- ***TrustAnchors***. The client can use this parameter to specify some set of certificates that must be at the top of any acceptable certificate chain. By using this parameter a client could, for example, say that only VeriSign Class 3 certificates were acceptable in this context.
- ***ResponseFlags***. This specifies various options as to how the server should respond (if it needs to sign or otherwise protect the response) and if a cached response is acceptable to the client.
- ***ValidationTime***. The client may want a validation performed as if it was a specific time, so that it can find if a certificate was valid at some point in the past. Note that SCVP does not allow for "speculative" validation, in terms of asking if a certificate will be valid in the future. This parameter allows the client to specify the validation time to be used by the server.
- ***IntermediateCerts***. The client can use this parameter to give additional certificates that can potentially be used to construct the certificate chain. The server is not obligated to use these certificates. This parameter is used where the client may have received a set of intermediate certificates from a communicating party, and is not certain that the SCVP server has possession of these certificates.
- ***RevInfos***. Like the IntermediateCerts parameter, the RevInfos parameter supplies extra information that may be needed to construct or validate the path. Instead of certificates, the RevInfos parameter supplies revocation information like OSCP responses, CRLs, or Delta CRLs.

8. X.509 BRIDGE CERTIFICATION SYSTEMS

In practice, large scale PKI systems proved to be more complex than could be easily handled under the X.509 hierarchical model. For example, Polk and Hastings [11] identified a number of policy complexities that presented difficulties when attempting to build a PKI system for the United States Federal Government. In this case, certainly one of the largest PKI projects ever undertaken, they found that the traditional model of a hierarchical certification system was simply unworkable. They state:

"The initial designs for a federal PKI were hierarchical in nature because of government's inherent hierarchical organizational structure. However, these initial PKI plans ran into several obstacles. There was no clear organization within the government that could be identified and agreed upon to run a governmental "root" CA. While the search for an appropriate organization dragged on, federal agencies began to deploy autonomous PKIs to enable their electronic processes. The search for a "root" CA for a hierarchical federal PKI was abandoned, due to the difficulties of imposing a hierarchy after the fact."

Their proposed solution to this problem was to use a "mesh CA" system to establish a Federal Bridge Certification Authority. This Bridge architecture has since been adopted in large PKI systems in Europe and the financial services community in the United States. The details of the European Bridge CA can be found at http://www.bridge-ca.org. This part of the chapter will detail the technical design of bridge CAs, and the various X.509 certificate features that enable bridges.

Mesh PKIs and Bridge CAs

Bridge CA architectures are implemented using a non-hierarchical certification structure called a Mesh PKI. The classic X.509 architecture joins together multiple PKI systems by subordinating them under a higher-level CA. All certificates chain up to this CA, and that CA essentially creates trust between the CAs below it. Mesh PKIs join together multiple PKI systems using a process called "cross certification" that does not create this type of hierarchy. To cross certify, the top level CA in a given hierarchy creates a certificate for an external CA called the Bridge CA. This bridge CA then becomes, in a manner of speaking, a sub-CA under the organization's CA. However, the Bridge CA also creates a certificate for the organizational CA, so it can also be viewed as a top level CA certifying that organizational CA.

The end result of this cross-certification process is that if, two organizations, A and B have joined the same bridge CA, the can both create certificate chains from their respective trusted CAs through the other organization's CA to end-entity certificates that it has created. These chains will be longer than traditional hierarchical chains, but have the same basic verifiable properties. Figure e39.7 shows how two organizations might be connected through a bridge CA, and what the resultant certificate chains look like.

In the case illustrated in Figure e39.7, a user that trusts certificates issued by PKI A (that is, PKI A Root is a "trust anchor") can construct a chain to certificates issued

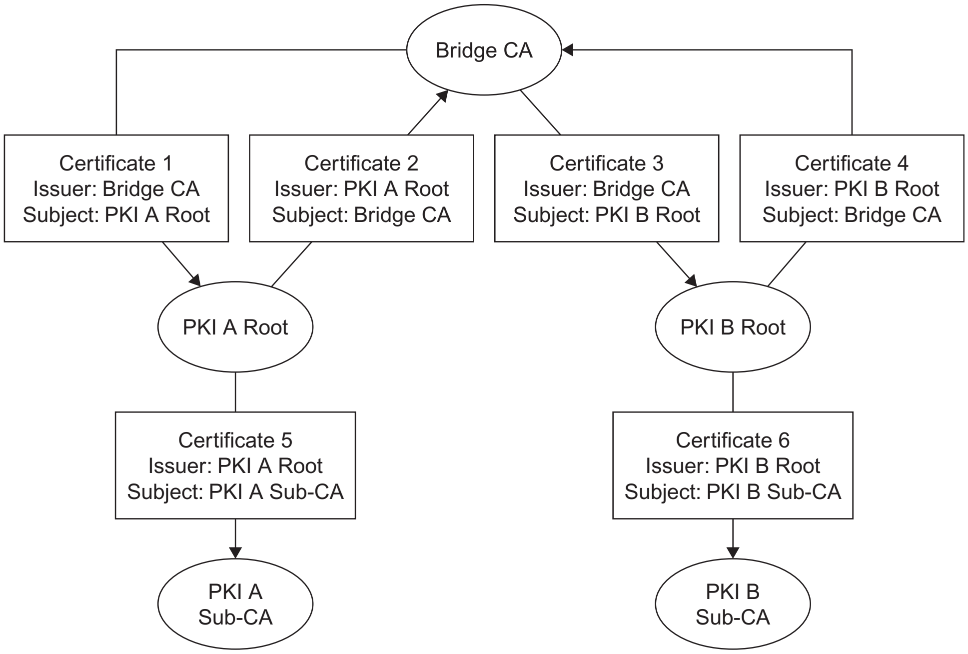

FIGURE e39.7 Showing the structure of two PKIs connected via a bridge CA.

by the PKI B SubCA, since it can verify Certificate 2 via its trust of the PKI A Root. Certificate 2 then chains to Certificate 3, which chains to Certificate 6. Certificate 6 then is a trusted issuer certificate for certificates issued by the PKI B SubCA.

Mesh architectures create two significant technical problems: path construction and policy evaluation. In a hierarchical PKI system, there is only one path from the root certificate to an end-entity certificate. Creating a certificate chain is as simple as taking the current certificate, locating the issuer in the subject field of another certificate, and repeating until the root is reached (completing the chain) or no certificate can be found (failing to construct the chain.) In a Mesh system, there are can now be cyclical loops where this process can fail to terminate with a failure or success. This is not a difficult problem to solve, but it is more complex to deal with than the hierarchical case.

Policy evaluation becomes much more complex in the Mesh case. In the hierarchical CA case, the top level CA can establish policies that are followed by Sub CAs, and these policies can be encoded into certificates in an unambiguous way. When multiple PKIs are joined by a bridge CA, these PKIs may have similar policies, but expressed with different names. PKI A and PKI B may both certify "medium assurance" CAs which perform a certain level of authentication before issuing certificates, but may have different identifiers for these policies. When joined by a bridge CA, clients may reasonably want to validate certificates issued by both CAs, and understand the policies that those certificates are issued under. The PolicyMapping technique allows similar policies under different names from disjoint PKIs to be translated at the bridge CA.

While none of these problems are insurmountable, they increase the complexity of certificate validation code, and helped drive the invention of server-based validation protocols like SCVP. These protocols delegate path discovery and validation to an external server, rather than require that applications integrate this functionality. While this may lower application complexity, the main benefit of this strategy is that questions of acceptable policies and translation can be configured at one central verification server rather than distributed to every application doing certificate validation.

9. X.509 CERTIFICATE FORMAT

The X.509 standard (and the related IETF RFCs) specify a set of data fields that must be present in a properly formatted certificate, a set of optional extension data fields that can be used to supply additional certificate information, how these fields must be signed, and how the signature data is encoded. All of these data fields (mandatory fields, optional fields, and the signature) are specified in Abstract Syntax Notation (aka ASN.1), a formal language that allows for exact definitions of the content of data fields and how those fields are arranged in a data structure. An associated specification, Determined Encoding Rules (DER) is used with specific certificate data and the

ASN.1 certificate format to create the actual binary certificate data. The ASN.1 standard is authoritatively defined in ITU Recommendation X.693. (For an introduction to ASN.1 and DER, see [kaliski])

X.509 V1 and V2 Format

The first X.509 certificate standard was published in 1988 as part of the broader X.500 directory standard. X.509 was intended to provide public key based access control to an X.500 directory, and defined a certificate format for that use. This format, now referred to as X.509 v1 defined a static format containing an X.400 Issuer name (the name of the CA), an X.400 Subject name, a validity period, the key to be certified, and the signature of the CA. While this basic format allowed for all the basic PKI operations, the format required that all names be in the X.400 form, and it did not allow for any other information to be added to the certificate. The X.509 v2 format added two more Unique ID fields, but did not fix the primary deficiencies of the v1 format. As it became clear that name formats would have to be more flexible, and certificates would have to accommodate a wider variety of information, work began on a new certificate format.

TABLE e39.5 Data Fields in an X.509 Version3 Certificate.

Version	The version of the standard used to format the certificate
Serial Number	A number, unique relative to the issuer, for this certificate
Signature Algorithm	The specific algorithm used to sign the certificate
Issuer	Name of the authority issuing the certificate
Validity	The time interval this certificate is valid for
Subject	The identity being certified
Subject Public Key	The key being bound to the Subject
Issuer Unique ID	Obsolete field
Subject Unique ID	Obsolete field
Extensions	A list of additional certificate attributes
Signature	A digital signature by the Issuer over the certificate data

X.509 V3 Format

The X.509 certificate specification was revised in 1996 to add an optional extension field which allows encoding a set of optional additional data fields into the certificate (see Table e39.5). While this change may seem minor, in fact it allowed certificates to carry a wide array of information useful for PKI implementation, and also for the certificate to contain multiple, non-X.400 identities. These extension fields allow for key usage policies, CA policy information, revocation pointers, and other relevant information to live in the certificate. The V3 format is the most widely used X.509 variant and is the basis for the certificate profile in RFC 3280 [5] issued by the Internet Engineering Task Force.

X.509 Certificate Extensions

This section is a partial catalog of common X.509 V3 extensions. There is no existing canonical directory of V3 extensions, so there are undoubtedly extensions in use outside this list. The most common extensions are defined in RFC 3280 [5], which contains the IETF certificate profile, used by S/MIME and many SSL/TLS implementations. These extensions address a number of deficiencies in the base X.509 certificate specification, and, in many cases, are essential for constructing a practical PKI system. In particular, the Certificate Policy, Policy Mapping, and Policy Constraints extensions form the basis for the popular bridge CA architectures.

Authority Key Identifier

The Authority Key Identifier extension identifies which specific private key owned by the certificate issuer was used to sign the certificate. The use of this extension allows a single issuer to use multiple private keys, and unambiguously identifies which key was used. This allows issuer keys to be refreshed without changing the issuer name, and enables handling events such as an issuer key being compromised or lost.

Subject Key Identifier

The Subject Key Identifier extension, like the Authority Key Identifier, indicates which subject key is contained in the certificate. This extension provides a way to quickly identify which certificates belong to a specific key owned by a subject. If the certificate is a CA certificate, the Subject Key Identifier can be used to construct chains by connecting a Subject Key Identifier with a matching Authority Key Identifier.

Key Usage

A CA may wish to issue a certificate that limits the use of a public key. This may lead to an increase in overall system security by segregating encryption keys from

An Agenda for Action to Define Key Usage Capabilities

The extension defines the following capabilities that need to be completed (Check All Tasks Completed):

_____1. ***digitalSignature*** – The key can be used to generate digital signatures.

_____2. ***nonRepudiation*** – Signatures generated from this key can be tied back to the signer in such a way that the signer cannot deny generating the signature. This capability is used in electronic transaction scenarios where it is important that signers cannot disavow a transaction.

_____3. ***keyEncipherment*** – The key can be used to wrap a symmetric key that is then used to bulk encrypt data. This is used in communications protocols, and applications like S/MIME where an algorithm like AES is used to encrypt data, and the public key in the certificate is used to then encipher that AES key. In practice, almost all encryption applications are structured in this manner, as public keys are generally unsuitable for the encryption of bulk data.

_____4. ***dataEncipherment*** – The key can be used to directly encrypt data. Because of algorithmic limitations of public encryption algorithms, the keyEncipherment technique is nearly always used instead of directly encrypting data.

_____5. ***keyAgreement*** – The key can be used to create a communication key between two parties. This capability can be used in conjunction with the encipherOnly and decipherOnly capabilities.

_____6. ***keyCertSign*** – The key can be used to sign another certificate. This is a crucial key usage capability, as it essentially allows creation of sub-certificates under this certificate, subject to basicConstraints. All CA certificates must have this usage bit set, and all end-entity certificates must NOT have it set.

_____7. ***cRLSign*** – The key can be used to sign a Certificate Revocation List (CRL). CA certificates may have this bit set, or they may delegate CRL creation to a different key, in which case this bit will be cleared.

_____8. ***encipherOnly*** – When the key is used for keyAgreement, the resultant key can only be used for encryption.

_____9. ***decipherOnly*** – When the key is used for keyAgreement, the resultant key can only be used for decryption.

signature keys, and even segregating signature keys by utilization. For example, an entity may have a key used for signing documents and a key used for decryption of documents. The signing key may be protected by a smart card mechanism that requires a PIN per signing, while the encryption key is always available when the user is logged in. The use of this extension allows the CA to express that the encryption key cannot be used to generate signatures, and notifies communicating users that they should not encrypt data with the signing public key. The key usage capabilities are defined in a bit field, which allows a single key to have any combination of the defined capabilities ("An Agenda For Action To Define Key Usage Capabilities").

Subject Alternative Name

This extension allows the certificate to define non-X.400 formatted identities for the subject. It supports a variety of name spaces, including email addresses, DNS names for servers, Electronic Document Interchange (EDI) party names, Uniform Resource Identifiers (URIs), and IP addresses, among others.

Policy Extensions

Three important X.509 certificate extensions (Certificate Policy, Policy Mapping, and Policy Constraints) form a complete system for communicating CA policies for how certificates are issued, revoked, and CA security is maintained. They are interesting in that they communicate information that is more relevant to business and policy decision making than the other extensions which are used in the technical processes of certificate chain construction and validation. As an example, a variety of CAs run multiple Sub-CAs that issue certificates according to a variety of issuance policies, ranging from "Low Assurance" to "High Assurance." The CA will typically formally define in a policy document all of it's operating policies, state them in practice statement, define an ASN.1 Object Identifier (OID) that names this policy, and distribute it to parties that will validate those certificates. The policy extensions allow CAs to attach a policy OID to its certificate, translate policy OIDs between PKIs, and limit the policies that can be used by sub CAs.

Certificate Policy

The Certificate Policy extension, if present in an issuer certificate, expresses the policies that are followed by the CA, both in terms of how identities are validated before certificate issuance, but also how certificates are revoked, and the operational practices that are used to insure integrity of the CA. These policies can be expressed in two ways: as an OID, which is a unique number that refers to

one given policy, and as a human-readable Certificate Practice Statement (CPS). One Certificate Policy extension can contain both the computer-sensible OID and a printable CPS. One special OID has been set aside for "AnyPolicy", which states that the CA may issue certificates under a free-form policy.

IETF RFC 2527 [12] gives a complete description of what should be present in a CA policy document and CPS. More details on the 2527 guidelines are given in the PKI Policy Description section.

Policy Mapping

The Policy Mapping extension contains two policy OIDs, one for the Issuer domain, the other for the Subject domain. When this extension is present, a validating party can consider the two policies identical, which is to say, the Subject OID, when present in the chain below the given certificate, can be considered to be the same as the policy named in the Issuer OID. This extension is used join together two PKI systems with functionally similar policies that have different policy reference OIDs.

Policy Constraints

The Policy Constraints extension enables a CA to disable policy mapping for CAs farther down in the chain, and also to require explicit policies in all the CAs below a given CA.

10. PKI POLICY DESCRIPTION

In many application contexts, it is important to understand how and when certifying authorities will issue and revoke certificates. Especially when bridge architectures are used, an administrator may need to evaluate a certifying authority's policy to determine how and when to trust certificates issued under that authority. For example, the United States Federal Bridge CA maintains a detailed specification of its operating procedures and requirements for bridged CAs at the US CIO office web site: (http://www.cio.gov/fpkipa/documents/FBCA_CP_RFC3647.pdf). Many other commercial CAs, such as VeriSign, maintain similar documents.

To make policy evaluation easier and more uniform, IETF RFC 2527 [12] specifies a standard format for certifying authorities to communicate their policy for issuing and revoking certificates. This specification divides a policy specification document into the following sections:

- ***Introduction***: This section describes the type of certificates that the CA issues, the applications that those certificates can be used in, and the OIDs used to identify CA policies. The Introduction also contains the contact information for the institution operating the CA.
- ***General Provisions:***This section details the legal obligations of the CA, any warranties given as to the reliability of the bindings in the certificate, and details as to the legal operation of the CA, including fees and relationship to any relevant laws.
- ***Identification and Authentication:***This section details how certificate requests are authenticated at the CA or RA, and how events like name disputes or revocation requests are handled.
- ***Operational Requirements:***This section details how the CA will react in case of key compromise, how it renews keys, how it publishes CRLs or other revocation information, how it is audited, and what records are kept during CA operation.
- ***Physical, Procedural, and Personnel Security Controls:***This section details how the physical location of the CA is controlled, and how employees are vetted.
- ***Technical Security Controls:***This section explains how the CA key is generated and protected though its lifecycle. CA key generation is typically done through an audited, recorded key generation ceremony to assure certificate users that the CA key was not copied or otherwise compromised during generation.
- ***Certificate and CRL Profile:***The specific policy OIDs published in certificates generated by the CA are given in this section. The information in this section is sufficient to accomplish the technical evaluation of a certificate chain published by this CA.
- ***Specification Administration:***The last section explains the procedures used to maintain and update the certificate policy statement itself.

These policy statements can be substantial documents. The Federal Bridge CA policy statement is at least 93 pages long, and other certificate authorities have similarly exhaustive documents. The aim of these statements is to provide enough legal backing for certificates produced by these CAs so that they can be used to sign legally binding contracts and automate other legally relevant applications.

11. PKI STANDARDS ORGANIZATIONS

The PKIX Working Group was established in the fall of 1995 with the goal of developing Internet standards to support X.509-based Public Key Infrastructures (PKIs). These specifications form the basis for numerous other IETF specifications that use certificates to secure various protocols, such as S/MIME (for secure email), TLS (for secured TCP connections), and IPSEC (for securing internet packets).

IETF PKIX

The PKIX working group has produced a complete set of specifications for an X.509 based PKI system. These specifications span 36 RFCs, and at least eight more RFCs are being considered by the group at the moment. In addition to the basic core of X.509 certificate profiles and verification strategies, the PKIX drafts cover the format of certificate request messages, certificates for arbitrary attributes (rather than for public keys), and a host of other certificate techniques.

Other IETF groups have produced a group of specifications that detail the usage of certificates in various protocols and applications. In particular, the S/MIME group, which details a method for encrypting email messages, and the SSL/TLS group, which details TCP/IP connection security, use X.509 certificates.

SDSI/SPKI

The Simple Distributed Security Infrastructure (SDSI) group was chartered in 1996 to design a mechanism for distributing public keys that would correct some of the perceived complexities inherent in X.509. In particular, the SDSI group aimed at building a PKI architecture [sdsi] that would not rely on a hierarchical naming system, but would instead work with local names that would not have to be enforced to be globally unique. The eventual SDSI design, produced by Ron Rivest and Butler Lampson, has a number of unique features:

- ***Public key-centric design***. The SDSI design uses the public key itself (or a hash of the key) as the primary indentifying name. SDSI signature objects can contain naming statements about the holder of a given key, but the names are not intended to be the "durable" name of a entity.
- ***Free-form namespaces***. SDSI imposes no restrictions on what form names must take, and imposes no hierarchy that defines a canonical namespace. Instead, any signer may assert identity information about the holder of a key, but no entity is required to the use (or believe) the identity bindings of any other particular signer. This allows each application to create a policy about who can create identities, how those identities are verified, and even what constitutes an identity.
- ***Support for groups and roles***. The design of many security constructions (access control lists, for example) often include the ability to refer to groups or roles instead of the identity of individuals. This allows access control and encryption operations to protect data for groups, which may be more natural in some situations.

The Simple Public Key Infrastructure (SPKI) group was started at nearly the same time, with goals similar to the SDSI effort. In X, the two groups were merged, and the SDSI/SPKI 2.0 specification was produced, incorporating ideas from both architectures.

IETF OpenPGP

The Pretty Good Privacy (PGP) public key system, created by Phillip Zimmermann, is a widely deployed PKI system that allows for the signing and encryption of files and email. Unlike the X.509 PKI architecture, the PGP PKI system uses the notion of a "Web of Trust" to bind identities to keys. The Web of Trust (WoT) [13] replaces the X.509 idea of identity binding via an authoritative server with identity binding via multiple semi-trusted paths.

In a WoT system, the end user maintains a database of matching keys and identities, each of which are given two trust ratings. The first trust rating denotes how trusted the binding between the key and the identity is, and the second denotes how trusted a particular identity is to "introduce" new bindings. Users can create and sign a certificate, and import certificates created by other users. Importing a new certificate is treated as an introduction. When a given identity and key in a database are signed by enough trusted identities, that binding is treated as trusted.

Because PGP identities are not bound by an authoritative server, there is also no authoritative server that can revoke a key. Instead, the PGP model states that the holder of a key can revoke that key by posting a signed revocation message to a public server. Any user seeing a properly signed revocation message then removes that key from their database. Because revocation messages must be signed, only the holder of the key can produce them, so it is impossible to produce a false revocation with out compromising the key. If an attacker does compromise the key, then production of a revocation message from that compromised key actually improves the security of the overall system, because it warns other users to not trust that key.

12. PGP CERTIFICATE FORMATS

To support the unique features of the Web of Trust system, PGP invented a very flexible packetized message format that can encode encrypted messages, signed messages, key database entries, key revocation messages, and certificates. This packetized design, described in IETF RFC 2440, allows a PGP certificate to contain a variable number of names and signatures, as opposed to the single-certification model used in X.509.

A PGP certificate (known as a transferrable public key) contains three main sections of packetized data. The first section contains the main public key itself, potentially followed by some set of relevant revocation packets. The next section contains a set of User ID packets, which ae identities to be bound to the main public key. Each User ID packet is optionally followed by a set of Signature packets, each of which contains an identity and a signature of the User ID packet and the main public key. Each of these Signature packets essentially forms an identity binding. Because each PGP certificate can contain any number of these User ID/Signature elements, a single certificate can assert that a public key is bound to multiple identities (for example, multiple email addresses that correspond to a single user), certified by multiple signers. This multiple signer approach enables the Web of Trust model. The last section of the certificate is optional and may contain multiple subkeys, which are single function keys (for example, an encryption only key) also owned by the holder of the main public key. Each of these subkeys must be signed by the main public key.

PGP Signature packets contain all the information needed to perform a certification, including time intervals for which the signature is valid. Figure e39.8 shows how the multi-name, multi-signature PGP format differs from the single-name with single-signature X.509 format.

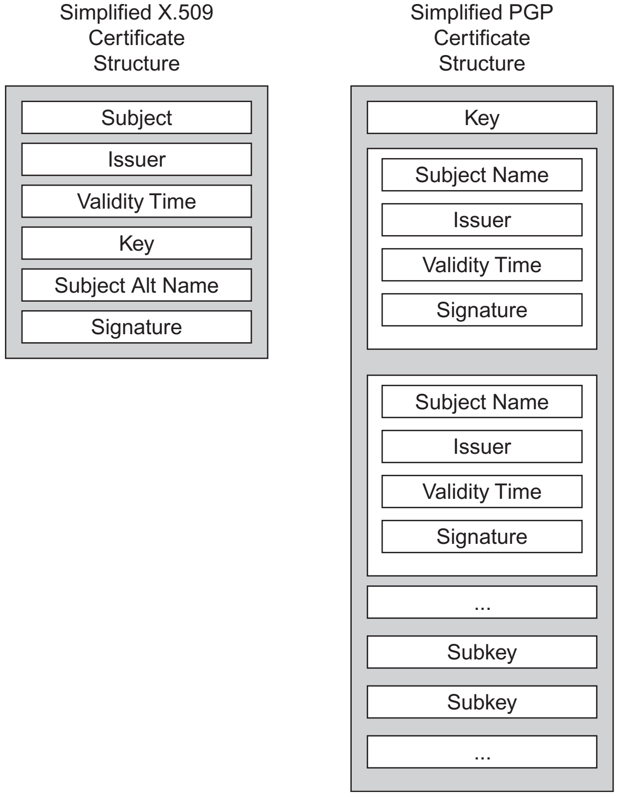

FIGURE e39.8 Comparing X.509 and PGP certificate structures.

13. PGP PKI IMPLEMENTATIONS

The PGP PKI system is implemented in commercial products sold by the PGP corporation, and several open source projects, including Gnu Privacy Guard (GPG) and OpenPGP. Thawte offers a Web of Trust service that connects people with "Web of Trust notaries" that can build trusted introductions. PGP Corporation operates a PGP Global Directory that contains PGP keys along with an email confirmation service to make key certification easier. The OpenPGP group (www.openpgp.org) maintains the IETF specification (RFC 2440) for the PGP message and certificate format.

14. W3C

The World Wide Web Consortium (W3C) standards group has published a series of standards on encrypting and signing XML documents. These standards, XML Signature and XML Encryption have a companion PKI specification called XKMS (XML Key Management Specification.)

The XKMS specification describes a meta-PKI that can be used to register, locate, and validate keys that may be certified by an outside X.509 CA, a PGP referrer, a SPKI key signer, or the XKMS infrastructure itself. The specification contains two protocol specifications, X-KISS (XML Key Information Service Specification) and X-KRSS (XML Key Registration Service Specification) X-KISS is used to find and validate a public key referenced in an XML document, and X-KRSS is used to register a public key so that it can be located by X-KISS requests.

15. IS PKI SECURE?

PKI has formed the basis of Internet security protocols like S/MIME for securing email, and the SSL/TLS protocols for securing communications between clients and web servers. The essential job of PKI in these protocols is binding a name, like an email address or domain name to a key that is controlled by that entity. As seen in this chapter, that job boils down to a CA issuing a certificate for an entity. The security of these systems then rests on the trustworthiness of the CAs trusted within an application. If a CA issues a set of bad certificates, the security of the entire system can be called into question.

The issue of a subverted CA was largely theoretical until attacks on the Comodo and DigiNotar CAs [2,3] in 2011. Both of these CAs discovered that an attacker had bypassed their internal controls and obtained certificates

for prominent Internet domains (google.com, yahoo.com.) These certificates were revoked, but the incident caused the major browser vendors to revisit their policies about what CA roots are trusted, and the removal of many CAs. In the case of DigiNotar, these attacks ultimately led to the bankruptcy of the company.

By attacking a CA and obtaining a false certificate for a given domain, the attacker can set up a fake version of the domain's web site, and using that certificate, create secure connections to clients that trust that CA's root certificate. This secure connection can be used as a "man-in-the-middle" server that reveals all traffic between the client (or clients) and the legitimate web site.

Can these attacks be prevented? There are research protocols such as "Perspectives" [14] that attempt to detect false certificates that might be signed by a legitimate CA. These protocols use third party repositories to track what certificates and keys are used by individual web sites. A change that is only noticed by some subset of users may indicate an attacker using a certificate to gain access to secured traffic.

Some other products that rely on PKI certification have introduced new features to make these attacks harder to execute. Google's Chrome browser also has recently incorporated security features [15] intended to foil attacks on PKI infrastructure. The Mozilla Foundation, owners of the Firefox browser, have instituted an audit and review system that requires all trusted CAs to attest they have specific kinds of security mechanisms in place to prevent the issuance of illegitimate certificates.

As a general principle, systems built to rely on PKI for security should understand the risks involved in CA compromise, and also understand how critical it is to control exposure to these kinds of attacks. One simple mechanism for doing this is to restrict the number of CAs that are trusted by the application. These large number of roots trusted by the average web browser is quite large, which makes auditing of the complete list of CAs difficult.

16. ALTERNATIVE PKI ARCHITECTURES

PKI systems have proven to be remarkably effective tools for some protocols, most notably SSL, which has emerged as the dominant standard for encrypting internet traffic. Deploying PKI systems for other types of applications or as a general key management system has not been as successful. The differentiating factor seems to be that PKI keys for machine end-entities (like web sites) do not encounter usability hurdles that emerge when issuing PKI keys for human end-entities. Peter Guttman [notdead] has a number of overviews of PKI that present the fundamental difficulties of classic X.509 PKI architectures. Alma Whitten and Doug Tygar [16] published "Why Johnny Can't Encrypt", a study of various users attempting to encrypt email messages using certificates. This study showed substantial user failure rates, due to the complexities of understanding certificate naming and validation practices. A subsequent study [17] showed similar results when using X.509 certificates with S/MIME encryption in Microsoft Outlook Express. The majority of the research on PKI alternatives has focused on making encryption easier to use and deploy.

17. MODIFIED X.509 ARCHITECTURES

Some researchers have proposed modifications or redesigns of the X.509 architecture to make obtaining a certificate easier, and lower the cost of operating applications that depend on certificates. The goal of these systems is often to allow internet based services to use certificate based signature and encryption service without requiring the user to consciously interact with certification services or even understand that certificates are being utililtzed.

Perlman and Kaufman's User-Centric PKI

Perlman and Kaufman proposed the "User-centric PKI" [Perlman], which allows the user to act as their own CA, with authentication provided through individual registration with service providers. It has several features that attempt to protect user privacy through allowing the user to pick what attributes are visible to a specific service provider.

Guttman's Plug and Play PKI

Guttman's proposed "Plug and Play PKI" [gutmann-pnp] provides for similar self-registration with a service provider and adds location protocols to establish how to contact certifying services. The goal is to build a PKI which provides a reasonable level of security and which is essentially transparent to the end user.

Callas' Self-Assembling PKI

In 2003, Jon Callas [18] proposed a PKI system that would use existing, standard PKI elements bound together by a "robot" server that would examine messages sent between users, and attempt to find certificates that could be used to secure the message. In the absence of an available certificate, the robot would create a key on behalf of the user, and send a message requesting authentication. This system has the benefit for speeding deployment of PKI systems for email authentication, but loses many of the strict authentication attributes that drove the development of the X.509 and IETF PKI standards.

18. ALTERNATIVE KEY MANAGEMENT MODELS

While PKI systems can be used for encryption as well as digital signature, these two applications have different operational characteristics. In particular, systems that use PKIs for encryption require that an encrypting party has the ability to locate certificates for its desired set of recipients. In digital signature applications, a signer only requires access to their own private key and certificate. The certificates required to verify the signature can be sent with the signed document, so there is no requirement for verifiers to locate arbitrary certificates. These difficulties have been identified as factors contributing to the difficulty of practical deployment of PKI based encryption systems like S/MIME.

In 1984, Adi Shamir [19] proposed an Identity-Based Encryption (IBE) system for email encryption. In the identity-based model, any string can be mathematically transformed into a public key, typically using some public information from a server. A message can then be encrypted with this key. To decrypt, the message recipient contacts the server and requests a corresponding private key. The server is able to mathematically derive a private key, which is returned to the recipient. Shamir disclosed how to perform a signature operation in this model, but did not give a solution for encryption.

This approach has significant advantages over the traditional PKI model of encryption. The most obvious is the ability to send an encrypted message without locating a certificate for a given recipient. There are other points of differentiation:

- ***Key recovery.*** In the traditional PKI model, if a recipient loses the private key corresponding to a certificate, all messages encrypted to that certificate's public key cannot be decrypted. In the IBE model, the server can recompute lost private keys. If messages must be recoverable for legal or other business reasons, PKI systems typically add mandatory secondary public keys that senders must encrypt messages to.
- ***Group support.*** Since any string can be transformed to a public key, a group name can be supplied instead of an individual identity. In the traditional PKI model, groups are either done by expanding a group to a set of individuals at encrypt time, or by issuing group certificates. Group certificates pose serious difficulties with revocation, since individuals can only be removed from a group as often as revocation is updated.

In 2001, Boneh and Franklin gave the first fully described secure and efficient method for IBE [20]. This was followed by a number of variant techniques, including Hierarchical Identity-Based Encryption (HIBE) and Certificateless Encryption. HIBE allows multiple key servers to be used, each of which control part of the namespace used for encryption. Certificateless [21] encryption adds the ability to encrypt to an end user using an identity, but in such a way that the key server cannot read messages. IBE systems have been commercialized, and are the subject of standards under the IETF (RFC 5091) and IEEE (1363.3).

19. SUMMARY

A Public Key Infrastructure (PKI) is the key management environment for public key information of a public key cryptographic system. As discussed in this chapter, there are three basic PKI architectures based on the number of Certificate Authorities (CAs) in the PKI, where users of the PKI place their trust (known as a user's trust point), and the trust relationships between CAs within a multi-CA PKI.

The most basic PKI architecture is one that contains a single CA that provides the PKI services (certificates, certificate status information, etc.) for all the users of the PKI. Multiple CA PKIs can be constructed using one of two architectures based on the trust relationship between the CAs. A PKI constructed with superior-subordinate CA relationships is called a hierarchical PKI architecture. Alternatively, a PKI constructed of peer-to-peer CA relationships is called a mesh PKI architecture.

Directory Architectures

As discussed in this chapter, early PKI development was conducted under the assumption a directory infrastructure (specifically a global X.500 directory) would be used to distribute certificates and certificate revocation lists (CRL). Unfortunately, the global X.500 directory did not emerge resulting in PKIs being deployed using various directory architectures based on how directory requests are serviced. If the initial directory cannot service a request, the directory can forward the request to other known directories using directory chaining. Another way a directory can resolve an unserviceable request is to return a referral to the initiator of the request indicating a different directory that might be able to service the request. If the directories cannot provide directory chaining or referrals, pointers to directory servers can be embedded in a PKI certificate using the Authority Information Access (AIA) and Subject Information Access (SIA) extensions. In general, all PKI users interface to the directory infrastructure using the Lightweight Directory Access Protocol (LDAP) irregardless of how the directory infrastructure is navigated.

Bridge Cas and Revocation Modeling

Bridge Certification Authorities (BCAs) provide the means to leverage the capabilities of existing corporate PKIs as well as Federal PKIs. Public key infrastructures (PKIs) are being fielded in increasing size and numbers, but operational experience to date has been limited to a relatively small number of environments. As a result, there are still many unanswered questions about the ways in which PKIs will be organized and operated in large scale systems. Some of these questions involve the ways in which individual certification authorities (CAs) will be interconnected. Others involve the ways in which revocation information will be distributed.

Most of the proposed revocation distribution mechanisms have involved variations of the original CRL scheme. Examples include the use of segmented CRLs and delta-CRLs. However, some schemes do not involve the use of any type of CRL (on-line certificate status protocols and hash chains).

A model of certificate revocation presents a mathematical model for describing the timings of validations by relying parties. The model is used to determine how request rates for traditional CRLs change over time. This model is then extended to show how request rates are affected when CRLs are segmented. This chapter also presented a technique for distributing revocation information, over-issued CRLs. Over-issued CRLs are identical to traditional CRLs but are issued more frequently. The result of over-issuing CRLs is to spread out requests from relying parties and thus to reduce the peak load on the repository.

A more efficient use of delta-CRLs uses the model described in a model of certificate revocation to analyze various methods of issuing delta-CRLs. It begins with an analysis of the "traditional" method of issuing delta-CRLs and shows that, in some circumstances, issuing delta-CRLs in this manner fails to provide the efficiency gains for which delta-CRLs were designed. A new method of issuing delta-CRLs, sliding window delta-CRLs, was presented. Sliding window delta-CRLs are similar to traditional delta-CRLs, but provide a constant amount of historical information. While this does not affect the request rate for delta-CRLs, it can significantly reduce the peak request rate for base CRLs. The chapter provided an analysis of sliding window delta-CRLs along with advice on how to select the optimal window size to use when issuing delta-CRLs.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The most important security protocols used on the Internet do not rely on PKI to bind names to keys – a crucial function that allows authentication of users and websites.
2. True or False? To understand how PKI systems function, it is not necessary to grasp the basics of public key cryptography.
3. True or False? The most important cryptographic operation in PKI systems is the digital signature.
4. True or False? Variants of the three operations used to construct digital signatures can also be used to encrypt data.
5. True or False? PKI systems solve the problem of associating meaningful names with essentially meaningless cryptographic keys.

Multiple Choice

1. What model is the most prevalent standard for certificate based PKIs, though the standard has evolved such that PKI-using applications on the Internet are mostly based on the set of IETF standards that have evolved and extended the ideas in X.509?
   A. X.510
   B. X.509
   C. X.511
   D. X.512
   E. X.513
2. What model specifies a system of Certifying Authorities (CAs) that issue certificates for end entities (users, web sites, or other entities that hold private keys.)?
   A. X.510
   B. X.509
   C. X.511
   D. X.512
   E. X.513
3. While, in theory, the _________________ is the entity that creates and validates certificates, in practice, it may be desirable or necessary to delegate the actions of user authentication and certificate validation to other servers.
   A. Evolution
   B. Residue class
   C. Peer-to-peer (P2P)
   D. Certification Authority
   E. Security
4. What certificate validation is a complex process, and can be done to several levels of confidence?
   A. X.509
   B. X.510

   C. X.511
   D. X.512
   E. X.513
5. The contents of the target certificate cannot be trusted until the signature on the certificate is validated, so the first step is to check the:
   A. Physical world
   B. Data retention
   C. Standardization
   D. Permutation
   E. Signature

1. STATUTORY AUTHORITIES

Here we discuss the important homeland security-related laws passed in the aftermath of the terrorist attacks. These laws are listed in Figure e57.1.

The USA PATRIOT Act of 2001 (PL 107-56)

Just 45 days after the September 11 attacks, Congress passed the USA PATRIOT Act of 2001 (also known as the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism Act of 2001). This Act, divided into 10 titles, expands law enforcement powers of the government and law enforcement authorities.[1] These titles are listed in Figure e57.2. A summary of the titles is shown in the sidebar, "Summary of USA PATRIOT Act Titles."

The Aviation and Transportation Security Act of 2001 (PL 107-71)

The series of September 11 attacks, perpetrated by 19 hijackers, killed 3000 people and brought commercial aviation to a standstill. It became obvious that enhanced laws and strong measures were needed to tighten aviation security. The Aviation and Transportation Security Act of 2001 transfers authority over civil aviation security from the Federal Aviation Administration (FAA) to the Transportation Security Administration (TSA).[2] With the passage of the Homeland Security Act of 2002, the TSA was later transferred to the Department of Homeland Security.

Key features of the act include the creation of an Undersecretary of Transportation for Security; federalization of airport security screeners; and the assignment of Federal Security Managers to each airport. Also included in the act are these provisions: airports provide for the screening of all checked baggage by explosive detection devices; allowing pilots to carry firearms; requiring the electronic transmission of passenger manifests on international flights prior to landing in the U.S.; requiring background checks, including national security checks, of persons who have access to secure areas at airports; and requiring that all federal security screeners be U.S. citizens.[3] These key features are highlighted in the Figure e57.3.

Enhanced Border Security and Visa Entry Reform Act of 2002 (PL 107-173)

This Act, divided into six titles, represents the most comprehensive immigration-related response to the terrorist threat.[4] The titles are listed in Figure e57.4. A summary of these titles is shown in the sidebar, "Summary of the Border Security and Visa Entry Reform Act of 2002."

TITLE I	Enhancing Domestic Security Against Terrorism
TITLE II	Enhanced Surveillance Procedures
TITLE III	International Money Laundering Abatement and Antiterrorist Financing Act of 2001
TITLE IV	Protecting the Border
TITLE V	Removing Obstacles to Investigate Terrorism
TITLE VI	Providing for Victims of Terrorism, Public Safety Officers, and their Families
TITLE VII	Increased Information Sharing for Critical Infrastructure Protection
TITLE VIII	Strengthening the Criminal Laws against Terrorism
TITLE IX	Improved Intelligence
TITLE X	Miscellaneous

FIGURE e57.2 USA PATRIOT Act titles.

Summary of USA PATRIOT Act Titles

Title I – Enhancing Domestic Security Against Terrorism
Increased funding for the technical support center at the Federal Bureau of Investigation, allowed military assistance to enforce prohibition in certain emergencies, and expanded National Electronic Crime Task Force Initiative.

Title II – Enhanced Surveillance Procedures
Authorized to intercept wire, oral, and electronic communications relating to terrorism, computer fraud and abuse offenses, to share criminal investigative information. It allowed seizure of voicemail messages pursuant to warrants and subpoenas for records of electronic communications. It provided delaying notice of the execution of a warrant, pen register and trap and trace authority under the Foreign Intelligence Surveillance Act, access to records and other items under FISA, interception of computer trespasser communications, and nationwide service of search warrants for electronic evidence.

Title III – International Money-laundering Abatement and Antiterrorist Financing Act of 2001
Special measures relating to the following three subtitles were created:

A. International Counter Money Laundering and Related Measures
B. Bank Secrecy Act Amendments and Related Improvements
C. Currency Crimes and Protection

Title IV – Protecting the Border
Special measures relating to the following three subtitles were created:

A. Protecting the Northern Border
B. Enhanced Immigration Provisions
C. Preservation of Immigration Benefits for Victims of Terrorism

Title V – Removing Obstacles to Investigating Terrorism
Attorney General and Secretary of State are authorized to pay rewards to combat terrorism. It allowed DNA identification of terrorists and other violent offenders, and allowed disclosure of information from National Center for Education Statistics (NCES) surveys.

Title VI – Providing for Victims of Terrorism, Public Safety Officers, and their Families
Special measures relating to the following subtitles were created:
A. Aid to Families of Public Safety Officers
B. Amendments to the Victims of Crime Act of 1984

Title VII – Increased Information Sharing for Critical Infrastructure Protection
Expansion of regional information sharing systems to facilitate federal, state, and local law enforcement response related to terrorist attacks.

Title VIII – Strengthening the Criminal Laws against Terrorism
Strengthened laws against terrorist attacks and other acts of violence against mass transportation systems and crimes committed at U.S. facilities abroad.

Provided for the development and support of cyber security forensic capabilities and expanded the biological weapons statute.

Title IX – Improved Intelligence
Responsibilities of Director of Central Intelligence regarding foreign intelligence collected under the Foreign Intelligence Surveillance Act of 1978.

Inclusion of international terrorist activities within scope of foreign intelligence under National Security Act of 1947.

Disclosure to Director of Central Intelligence of foreign intelligence-related information with respect to criminal investigations.

Foreign terrorist asset tracking center.

Title X – Miscellaneous
Review of the Department of Justice.
A. Definition of electronic surveillance.
B. Venue in money-laundering cases.
C. Automated fingerprint identification system at overseas consular posts and points of entry to the United States.
D. Critical infrastructures protection.

Creation of an Undersecretary of Transportation for Security
Federalization of Airport Security Screeners
Assignment of Federal Security Managers
Airport Screening by Explosion Detection Devices
Allowing Pilots to Carry Firearms
Electronic Transmission of Passenger Manifests on International Flights

FIGURE e57.3 Key features of the Aviation and Transportation Security Act of 2001.

TITLE I	Funding
TITLE II	Interagency Information Sharing
TITLE III	Visa Issuance
TITLE IV	Inspection and Admission of Aliens
TITLE V	Removing the Obstacles to Investigate Terrorism
TITLE VI	Foreign Students and Exchange Visitors
TITLE VII	Miscellaneous

FIGURE e57.4 Border Security and Visa Entry Reform Act of 2002.

Summary of the Border Security and Visa Entry Reform Act of 2002

Title I – Funding
The Act provides for additional staff and training to increase security on both the northern and southern borders.

Title II – Interagency Information Sharing
The Act requires the President to develop and implement an interoperable electronic data system to provide current and immediate access to information contained in the databases of federal law enforcement agencies and the intelligence community that is relevant to visa issuance determinations and determinations of an alien's admissibility or deportability.

Title III – Visa Issuance
This requires consular officers issuing a visa to an alien to transmit an electronic version of the alien's visa file to the INS so that the file is available to immigration inspectors at U.S. ports of entry before the alien's arrival.

This Act requires the Attorney General and the Secretary of State to begin issuing machine-readable, tamper-resistant travel documents with biometric identifiers.

Title IV – Inspection and Admission of Aliens
It requires the President to submit to Congress a report discussing the feasibility of establishing a North American National Security Program to enhance the mutual security and safety of the U.S., Canada, and Mexico.

It also requires that all commercial flights and vessels coming to the U.S. from any place outside the country must provide to manifest information about each passenger, crew member, and other occupant prior to arrival in the U.S. In addition, each vessel or aircraft departing from the U.S. for any destination outside the U.S. must provide manifest information before departure.

Title VI – Foreign Students and Exchange Visitors
It requires the Attorney General, in consultation with the Secretary of State, to establish an electronic means to monitor and verify the various steps involved in the admittance to the U.S. of foreign students, such as: the issuance of documentation of acceptance of a foreign student by an educational institution or exchange visitor program.

Title VII – Miscellaneous
The Act requires the Comptroller General to conduct a study to determine the feasibility of requiring every nonimmigrant alien in the U.S. to provide the INS, on an annual basis, with a current address, and where applicable, the name and address of an employer.

It requires the Secretary of State and the INS Commissioner, in consultation with the Director of the Office of Homeland Security, to conduct a study on the procedures necessary for encouraging or requiring countries participating in the Visa Waiver Program to develop an intergovernmental network of interoperable electronic data systems.

Public Health Security, Bioterrorism Preparedness & Response Act of 2002 (PL 107–188)

The Act authorizes funding for a wide range of public health initiatives.[5] Title I of the Act addresses the national need to combat threats to public health, and to provide grants to state and local governments to help them prepare for public health emergencies, including emergencies resulting from acts of bioterrorism. The Act establishes opportunities for grants and cooperative agreements for states and local governments to conduct evaluations of public health emergency preparedness, and enhance public health infrastructure and the capacity to prepare for and respond to those emergencies. Other grants support efforts to combat antimicrobial resistance, improve public health laboratory capacity, and support collaborative efforts to detect, diagnose, and respond to acts of bioterrorism. The Act also addresses other related public health security issues. Some of these provisions include:

- New controls on biological agents and toxins
- Additional safety and security measures affecting the nation's food and drug supply
- Additional safety and security measures affecting the nation's drinking water
- Measures affecting the Strategic National Stockpile and development of priority countermeasures to bioterrorism

Homeland Security Act of 2002 (PL 107-296)

This landmark Act establishes a new Executive Branch agency, the U.S. Department of Homeland Security (DHS), and consolidates the operations of 22 existing federal agencies.[6] The primary mission of the DHS is given in Figure e57.5. As a part of this act, a directorate (see checklist, "An Agenda For Action For Implementing The Directorate Of Information Analysis And Infrastructure

5. "Public Health Security, Bioterrorism Preparedness & Response Act of 2002," U.S. Government Printing Office, http://frwebgate.access.gpo.gov/cgi-bin/getdoc.cgi?dbname=107_cong_public_laws&docid=f:publl88.107 (downloaded 10/20/2008).

Prevent Terrorist Attacks
Reduce the Vulnerability of the United States to Terrorism
Minimize the damage, and assist in recovery from terrorist attacks that do occur in the United States

FIGURE e57.5 DHS mission.

Protection") of information analysis and infrastructure protection was set up.

E-Government Act of 2002 (PL 107-347)

The E-Government Act of 2002 establishes a Federal Chief Information Officers Council to oversee government information and services, and creation of a new Office of Electronic Government within the Office of Management and Budget.[8] The purposes of the Act are:

- To provide effective leadership of federal government efforts to develop and promote electronic government services and processes by establishing an Administrator of a new Office of Electronic Government within the Office of Management and Budget.

An Agenda for Action for Implementing the Directorate of Information Analysis and Infrastructure Protection

The primary role of this directorate is to[7] (Check All Tasks Completed):

_____**1.** Access, receive, and analyze law enforcement information, intelligence information, and other information from agencies of the federal government, state and local government agencies (including law enforcement agencies), and private sector entities, and to integrate such information in order to :

_____**a.** Identify and assess the nature and scope of terrorist threats to the homeland.

_____**b.** Detect and identify threats of terrorism against the United States.

_____**c.** Understand such threats in light of actual and potential vulnerabilities of the homeland.

_____**2.** Carry out comprehensive assessments of the vulnerabilities of the key resources and critical infrastructure of the United States, including the performance of risk assessments to determine the risks posed by particular types of terrorist attacks within the United States (including an assessment of the probability of success of such attacks and the feasibility and potential efficacy of various countermeasures to such attacks).

_____**3.** Integrate relevant information, analyses, and vulnerability assessments (whether such information, analyses, or assessments are provided or produced by the Department or others) in order to identify priorities for protective and support measures by the Department, other agencies of the federal government, state and local government agencies and authorities, the private sector, and other entities.

_____**4.** Ensure, pursuant to section 202, the timely and efficient access by the Department to all information necessary to discharge the responsibilities under this section, including obtaining such information from other agencies of the federal government.

_____**5.** Develop a comprehensive national plan for securing the key resources and critical infrastructure of the United States, including power production, generation, and distribution systems, information technology and telecommunications systems (including satellites), electronic financial and property record storage and transmission systems, emergency preparedness communications systems, and the physical and technological assets that support such systems

_____**6.** Recommend measures necessary to protect the key resources and critical infrastructure of the

7. "Homeland Security Act of 2002," Homeland Security, www.dhs.gov/xabout/laws/law_regulation_rule_0011.shtm (downloaded 10/20/2008).

8. "E-Government Act of 2002," U.S. Government Printing Office, http://frwebgate.access.gpo.gov/cgi-bin/getdoc.cgi?dbname=107_cong_public_laws&docid=f:publ347.107.pdf (downloaded 10/20/2008).

United States in coordination with other agencies of the federal government and in cooperation with state and local government agencies and authorities, the private sector, and other entities.

_____**7.** Administer the Homeland Security Advisory System, including:

_____**a.** Exercising primary responsibility for public advisories related to threats to homeland security.

_____**b.** In coordination with other agencies of the federal government, providing specific warning information, and advice about appropriate protective measures and countermeasures, to state and local government agencies and authorities, the private sector, other entities, and the public.

_____**8.** Review, analyze, and make recommendations for improvements in the policies and procedures governing the sharing of law enforcement information, intelligence information, intelligence-related information, and other information relating to homeland security within the federal government and between the federal government and state and local government agencies and authorities.

_____**9.** Disseminate, as appropriate, information analyzed by the Department within the Department, to other agencies of the federal government with responsibilities relating to homeland security, and to agencies of state and local governments and private sector entities with such responsibilities in order to assist in the deterrence, prevention, preemption of, or response to, terrorist attacks against the United States.

_____**10.** Consult with the Director of Central Intelligence and other appropriate intelligence, law enforcement, or other elements of the federal government to establish collection priorities and strategies for information, including law enforcement-related information, relating to threats of terrorism against the United States through such means as the representation of the Department in discussions regarding requirements and priorities in the collection of such information.

_____**11.** Consult with state and local governments and private sector entities to ensure appropriate exchanges of information, including law enforcement-related information, relating to threats of terrorism against the United States.

_____**12.** Ensure that:

_____**a.** Any material received pursuant to this Act is protected from unauthorized disclosure and handled and used only for the performance of official duties.

_____**b.** Any intelligence information under this Act is shared, retained, and disseminated consistent with the authority of the Director of Central Intelligence to protect intelligence sources and methods under the National Security Act of 1947 (50 U.S.C. 401 et seq.) and related procedures and, as appropriate, similar authorities of the Attorney General concerning sensitive law enforcement information.

_____**13.** Request additional information from other agencies of the federal government, state and local government agencies, and the private sector relating to threats of terrorism in the United States, or relating to other areas of responsibility assigned by the Secretary, including the entry into cooperative agreements through the Secretary to obtain such information.

_____**14.** Establish and utilize, in conjunction with the chief information officer of the Department, a secure communications and information technology infrastructure, including data mining and other advanced analytical tools, in order to access, receive, and analyze data and information in furtherance of the responsibilities under this section, and to disseminate information acquired and analyzed by the Department, as appropriate.

_____**15.** Ensure, in conjunction with the chief information officer of the Department, any information databases and analytical tools developed or utilized by the Department:

_____**a.** Are compatible with one another and with relevant information databases of other agencies of the federal government.

_____**b.** Treat information in such databases in a manner that complies with applicable federal law on privacy.

_____**16.** Coordinate training and other support to the elements and personnel of the Department, other agencies of the federal government, and state and local governments that provide information to the Department, or are consumers of information provided by the Department, in order to facilitate the identification and sharing of information revealed in their ordinary duties and the optimal utilization of information received from the Department.

_____**17.** Coordinate with elements of the intelligence community and with federal, state, and local law enforcement agencies, and the private sector, as appropriate.

_____**18.** Provide intelligence and information analysis and support to other elements of the Department.

_____**19.** Perform such other duties relating to such responsibilities as the Secretary may provide.

- To promote use of the Internet and other information technologies to provide increased opportunities for citizen participation in government.
- To promote interagency collaboration in providing electronic government services, where this collaboration would improve the service to citizens by integrating related functions, and in the use of internal electronic government processes, where this collaboration would improve the efficiency and effectiveness of the processes.
- To improve the ability of the government to achieve agency missions and program performance goals.
- To promote the use of the Internet and emerging technologies within and across government agencies to provide citizen-centric government information and services.
- To reduce costs and burdens for businesses and other government entities.
- To promote better informed decision-making by policy makers.
- To promote access to high quality government information and services across multiple channels.
- To make the federal government more transparent and accountable.
- To transform agency operations by utilizing, where appropriate, best practices from public and private sector organizations.
- To provide enhanced access to government information and services in a manner consistent with laws regarding protection of personal privacy, national security, records retention, access for persons with disabilities, and other relevant laws.

Title III of the Act is known as the Federal Information Security Management Act of 2002. This act applies to the national security systems, that include any information systems used by an agency or a contractor of an agency involved in intelligence activities; cryptology activities related to the nation's security; command and control of military equipment that is an integral part of a weapon or weapons system or is critical to the direct fulfillment of military or intelligence missions. Nevertheless, this definition does not apply to a system that is used for routine administrative and business applications (including payroll, finance, logistics, and personnel management applications). The purposes of this Title are to:

- Provide a comprehensive framework for ensuring the effectiveness of information security controls over information resources that support federal operations and assets.
- Recognize the highly networked nature of the current federal computing environment and provide effective government-wide management and oversight of the related information security risks, including coordination of information security efforts throughout the civilian, national security, and law-enforcement communities.
- Provide for development and maintenance of minimum controls required to protect federal information and information systems.
- Provide a mechanism for improved oversight of federal agency information security programs.
- Acknowledge that commercially developed information security products offer advanced, dynamic, robust, and effective information security solutions, reflecting market solutions for the protection of critical information infrastructures important to the national defense and economic security of the nation that are designed, built, and operated by the private sector.
- Recognize that the selection of specific technical hardware and software information security solutions should be left to individual agencies from among commercially developed products.

2. HOMELAND SECURITY PRESIDENTIAL DIRECTIVES

Presidential directives are issued by the National Security Council and are signed or authorized by the President. A series of Homeland Security Presidential Directives (HSPDs) were issued by President George W. Bush on matters pertaining to Homeland Security[9] :

- HSPD 1: Organization and Operation of the Homeland Security Council. Ensures coordination of all homeland security-related activities among executive departments and agencies and promotes the effective development and implementation of all homeland security policies.
- HSPD 2: Combating Terrorism Through Immigration Policies. Provides for the creation of a task force which will work aggressively to prevent aliens who engage in or support terrorist activity from entering the United States and to detain, prosecute, or deport any such aliens who are within the United States.
- HSPD 3: Homeland Security Advisory System. Establishes a comprehensive and effective means to disseminate information regarding the risk of terrorist acts to federal, state, and local authorities and to the American people.
- HSPD 4: National Strategy to Combat Weapons of Mass Destruction. Applies new technologies,

9. "Homeland Security presidential directives," Homeland Security, https://www.drii.org/professional_prac/profprac_appendix.html#BUSINESS_CONTINUITY_PLANNING_INFORMATION, 2008 (downloaded 10/24/2008).

increased emphasis on intelligence collection and analysis, strengthens alliance relationships, and establishes new partnerships with former adversaries to counter this threat in all of its dimensions.

- HSPD 5: Management of Domestic Incidents. Enhances the ability of the United States to manage domestic incidents by establishing a single, comprehensive national incident management system.
- HSPD 6: Integration and Use of Screening Information. Provides for the establishment of the Terrorist Threat Integration Center.
- HSPD 7: Critical Infrastructure Identification, Prioritization, and Protection. Establishes a national policy for federal departments and agencies to identify and prioritize United States critical infrastructure and key resources and to protect them from terrorist attacks.
- HSPD 8: National Preparedness. Identifies steps for improved coordination in response to incidents. This directive describes the way federal departments and agencies will prepare for such a response, including prevention activities during the early stages of a terrorism incident. This directive is a companion to HSPD-5.
- HSPD 8 Annex 1: National Planning. Further enhances the preparedness of the United States by formally establishing a standard and comprehensive approach to national planning.
- HSPD 9: Defense of United States Agriculture and Food. Establishes a national policy to defend the agriculture and food system against terrorist attacks, major disasters, and other emergencies.
- HSPD 10: Biodefense for the 21st Century. Provides a comprehensive framework for our nation's Biodefense.
- HSPD 11: Comprehensive Terrorist-Related Screening Procedures. Implements a coordinated and comprehensive approach to terrorist-related screening that supports homeland security, at home and abroad. This directive builds upon HSPD 6.
- HSPD 12: Policy for a Common Identification Standard for Federal Employees and Contractors. Establishes a mandatory, government-wide standard for secure and reliable forms of identification issued by the federal government to its employees and contractors (including contractor employees).
- HSPD 13: Maritime Security Policy. Establishes policy guidelines to enhance national and homeland security by protecting U.S. maritime interests.
- HSPD 15: U.S. Strategy and Policy in the War on Terror.
- HSPD 16: Aviation Strategy. Details a strategic vision for aviation security while recognizing ongoing efforts, and directs the production of a National Strategy for Aviation Security and supporting plans.
- HSPD 17: Nuclear Materials Information Program.
- HSPD 18: Medical Countermeasures against Weapons of Mass Destruction. Establishes policy guidelines to draw upon the considerable potential of the scientific community in the public and private sectors to address medical countermeasure requirements relating to CBRN threats.
- HSPD 19: Combating Terrorist Use of Explosives in the United States. Establishes a national policy, and calls for the development of a national strategy and implementation plan, on the prevention and detection of, protection against, and response to terrorist use of explosives in the United States.
- HSPD 20: National Continuity Policy. Establishes a comprehensive national policy on the continuity of federal government structures and operations and a single National Continuity Coordinator responsible for coordinating the development and implementation of federal continuity policies.
- HSPD 20 Annex A: Continuity Planning. Assigns executive departments and agencies to a category commensurate with their COOP/COG/ECG responsibilities during an emergency.
- HSPD 21: Public Health and Medical Preparedness. Establishes a national strategy that will enable a level of public health and medical preparedness sufficient to address a range of possible disasters.
- HSPD 23: National Cyber Security Initiative.
- HSPD 24: Biometrics for Identification and Screening to Enhance National Security. Establishes a framework to ensure that federal executive departments use mutually compatible methods and procedures regarding biometric information of individuals, while respecting their information privacy and other legal rights.

3. ORGANIZATIONAL ACTIONS

These laws and homeland security presidential directives called for deep and fundamental organizational changes to the executive branch of the government. The Homeland Security Act of 2002 established a new Executive Branch agency, the U.S. Department of Homeland Security (DHS), and consolidated the operations of 22 existing federal agencies.[10] This Department's overriding and urgent missions are (1) to lead the unified national effort to secure the country and preserve our freedoms, and (2) to prepare for and respond to all hazards and disasters. The citizens of the United States

10. "Public Health Security, Bioterrorism Preparedness & Response Act of 2002," U.S. Government Printing Office, http://frwebgate.access.gpo.gov/cgi-bin/getdoc.cgi?dbname=107_cong_public_laws&docid=f:publ188.107 (downloaded 10/20/2008).

must have the utmost confidence that the Department can execute both of these missions.

Faced with the challenge of strengthening the components to function as a unified Department, DHS must coordinate centralized, integrated activities across components that are distinct in their missions and operations. Thus, sound and cohesive management is the key to department-wide and component-level strategic goals. We seek to harmonize our efforts as we work diligently to accomplish our mission each and every day.

The Department of Homeland Security is headed by the Secretary of Homeland Security. It has various departments, including management, science and technology, health affairs, intelligence and analysis, citizenship and immigration services, and national cyber security center.

Department of Homeland Security Subcomponents

There are various subcomponents of The Department of Homeland Security that are involved with Information Technology Security.[11] These include the following:

- The Office of Intelligence and Analysis is responsible for using information and intelligence from multiple sources to identify and assess current and future threats to the United States.
- The National Protection and Programs Directorate houses offices of the Cyber Security and Communications Department.
- The Directorate of Science and Technology is responsible for research and development of various technologies, including information technology.
- The Directorate for Management is responsible for department budgets and appropriations, expenditure of funds, accounting and finance, procurement, human resources, information technology systems, facilities and equipment, and the identification and tracking of performance measurements.
- The Office of Operations Coordination works to deter, detect, and prevent terrorist acts by coordinating the work of federal, state, territorial, tribal, local, and private-sector parties and by collecting and turning information from a variety of sources. It oversees the Homeland Security Operations Center (HSOC), which collects and fuses information from more than 35 federal, state, local, tribal, territorial, and private-sector agencies.

11. "Public Health Security, Bioterrorism Preparedness & Response Act of 2002," U.S. Government Printing Office, http://frwebgate.access.gpo.gov/cgi-bin/getdoc.cgi?dbname = 107_cong_public_laws&docid=f:publ188.107 (downloaded 10/20/2008).

State and Federal Organizations

There are various organizations that support information sharing at the state and the federal levels. The Department of Homeland Security through the Office of Intelligence and Analysis provides personnel with operational and intelligence skills. The support to the state agencies is tailored to the unique needs of the locality and serves to:

- Help the classified and unclassified information flow
- Provide expertise
- Coordinate with local law enforcement and other agencies
- Provide local awareness and access

As of March 2008, there were 58 fusion centers around the country. The Department has provided more than $254 million from FY 2004–2007 to state and local governments to support the centers.

The Homeland Security Data Network (HSDN), which allows the federal government to move information and intelligence to the states at the Secret level, is deployed at 19 fusion centers. Through HSDN, fusion center staff can access the National Counterterrorism Center (NCTC), a classified portal of the most current terrorism-related information.

There are various organizations at the state levels that support the homeland security initiatives. These organizations vary in their size and budget from very large independently run departments to a department that is a part of a larger related department. As an example, California has the Office of Management Services that is responsible for any emergencies in the state of California. The Governor's Office of Homeland Security is responsible for the coordination among different departments to secure the state against potential terrorist threats. Very specific to IT security, the California Office of Information Security and Privacy Protection is functional.

The Governor's Office of Homeland Security

The Governor's Office of Homeland Security (OHS) acts as the Cabinet-level state office for the prevention of and preparation for a potential terrorist event.[12] OHS serves a diverse set of federal, state, local, private sector, and tribal entities by taking an "all-hazards" approach to reducing risk and increasing responder capabilities.

Because California is prone to floods, fires, and earthquakes in addition to the potential for an attack using manmade weapons of mass destruction, OHS is committed to contributing to a comprehensive, well-planned all-

12. "The Governor's Office of Homeland Security (OHS)," www.homeland.ca.gov/(downloaded 10/24/2008).

hazards strategy to prevent, prepare for, respond to, and recover from any possible emergency. OHS is responsible for several key state functions, including[13] :

- Analysis and dissemination of threat-related information
- Protection of California's critical infrastructure
- Management of the state's homeland security grants
- S/B training and exercising of first responders for terrorism events

California Office of Information Security and Privacy Protection

The California Office of Information Security and Privacy Protection (OISPP) unites consumer privacy protection with the oversight of government's responsible management of information. OISPP provides services to consumers, recommends practices to business, and provides policy direction, guidance, and compliance monitoring to state government.[14]

OISPP was established within the State and Consumer Services Agency by Chapter 183 of the Statutes of 2007 (Senate Bill 90), effective January 1, 2008. This legislation merged the Office of Privacy Protection, which opened in 2001 in the Department of Consumer Affairs with a mission of identifying consumer problems in the privacy area and encouraging the development of fair information practices, and the State Information Security Office, established within the Department of Finance with a mission of overseeing information security, risk management, and operational recovery planning within state government.[15]

Private Sector Organizations for Information Sharing

Intelligence sharing and analysis groups have been set up in many private infrastructure industries. As an example, National Electric Reliability Council has such a group, Electricity Sector Information Sharing and Analysis Center (ESISAC), which serves the electricity sector by facilitating communications between sector participants, federal governments, and other critical infrastructure organizations. It is the job of the ESISAC to promptly disseminate threat indications, analyses, and warnings, together with interpretations, to assist electricity sector participants take protective actions. Similarly, many other organizations in other infrastructure sectors are also members of an ISAC.

There are other organizations that share information among the member companies on issues related to incident response (see sidebar, "National Commission on Terrorist Attacks Upon the United States [The 9-11 Commission]"). These organizations include FIRST, the Forum of Incident Response and Security Teams,[16] which has as its members major corporations from all over the world. The FBI encourages organizations from the private sector to become members of InfraGard to encourage exchange of information among the members.[17]

4. SUMMARY

Within about a year after the terrorist attacks, Congress passed various new laws, such as The USA PATRIOT Act, Aviation and Transportation Security Act, Enhanced Border Security and Visa Entry Reform Act, Public Health Security, Bioterrorism Preparedness & Response Act, Homeland Security Act, and E-Government Act, and introduced sweeping changes to homeland security provisions and to the existing security organizations. The executive branch of the government also issued a series of Homeland Security Presidential Directives (HSPDs) to maintain domestic security. These laws and directives are comprehensive and contain detailed provisions to make the United States secure. For example, HSPD 5 enhances the ability of the United States to manage domestic incidents by establishing a single, comprehensive national incident management system.

These laws and homeland security presidential directives call for deep and fundamental organizational changes to the executive branch of the government. For example, the Homeland Security Act of 2002 established a new Executive Branch agency, the U.S. Department of Homeland Security (DHS), and consolidated the operations of 22 existing federal agencies. Intelligence-sharing and analysis groups have been set up in many private infrastructure industries as well. For example, the National Electric Reliability Council has such a group, the Electricity Sector Information Sharing and Analysis Center (ESISAC), which serves the electricity sector by facilitating communications between sector participants, federal governments, and other critical infrastructure organizations.

Congress charted the "National Commission on Terrorist Attacks Upon the United States (The 9-11 Commission)" on November 27, 2002, to provide a "full and complete accounting" of the attacks of September 11, 2001, and recommendations as to how to prevent such attacks in the future. On July 22, 2004, the 9-11 Commission issued its final report, which included 41

National Commission on Terrorist Attacks Upon the United States (The 9-11 Commission)

Congress charted the National Commission on Terrorist Attacks Upon the United States (known as the 9-11 Commission) by Public Law 107-306, signed by the President on November 27, 2002, to provide a "full and complete accounting" of the attacks of September 11, 2001 and recommendations as to how to prevent such attacks in the future.[18] On July 22, 2004, the 9-11 Commission issued its final report, which included 41 wide-ranging recommendations to help prevent future terrorist attacks.[19] Many of these recommendations were put in place with the passage of the Intelligence Reform and Terrorism Prevention Act of 2004 (PL 108-458), which brought about significant reorganization of the intelligence community. Soon after the Democratic Party came into the majority in the House of Representatives, the 110th Congress passed another act, Implementing Recommendations of the 9-11 Commission Act of 2007 (PL 110-53). This section is subdivided into the following four subsections:

1. Creation of the National Commission on Terrorist Attacks Upon the United States (the 9-11 Commission)
2. Final Report of the National Commission on Terrorist Attacks Upon the United States (the 9-11 Commission Report)
3. Intelligence Reform and Terrorism Prevention Act of 2004 (PL 108-458)
4. Implementing Recommendations of the 9-11 Commission Act of 2007 (PL 110-53)

Creation of the National Commission on Terrorist Attacks Upon the United States (The 9-11 Commission)

Congress created the National Commission on Terrorist Attacks Upon the United States (known as the 9-11 Commission) to provide a "full and complete accounting" of the terrorist attacks and recommendations as to how to prevent such attacks in the future.[20] Specifically, the Commission was required to investigate "facts and circumstances relating to the terrorist attacks of September 11, 2001," including those relating to intelligence agencies; law-enforcement agencies; diplomacy; immigration, nonimmigrant visas, and border control; the flow of assets to terrorist organizations; commercial aviation; the role of congressional oversight and resource allocation; and other areas determined relevant by the Commission for its inquiry.

The Commission was composed of 10 members, of whom not more than five members of the Commission were from the same political party.

In response to the requirements under law, the Commission organized work teams to address each of the following eight topics[21]:

1. Al Qaeda and the organization of the 9-11 attack
2. Intelligence collection, analysis, and management (including oversight and resource allocation)
3. International counterterrorism policy, including states that harbor or harbored terrorists, or offer or offered terrorists safe havens
4. Terrorist financing
5. Border security and foreign visitors
6. Law enforcement and intelligence collection inside the United States
7. Commercial aviation and transportation security, including an Investigation into the circumstances of the four hijackings
8. The immediate response to the attacks at the national, state, and local levels, including issues of continuity of government.

Final Report of the National Commission on Terrorist Attacks Upon the United States (The 9-11 Commission Report)

The 9-11 Commission interviewed more than 1000 individuals in 10 countries and held at least 10 days of public hearings, receiving testimony from more than 110 federal, state, and local officials and experts from the private sector. The Commission issued three subpoenas to government agencies: the Federal Aviation Administration (FAA), the Department of Defense, and the City of New York. On July 22, 2004, the 9-11 Commission issued its final report, which included 41 wide-ranging recommendations to help prevent future terrorist attacks. This report covers both general and specific findings. Here is the summary of their general findings:

Since the plotters were flexible and resourceful, we cannot know whether any single step or series of steps would have defeated them. What we can say with confidence is that none of the measures adopted by the U.S. government from 1998 to 2001 disturbed or even delayed the progress of the al Qaeda plot. Across the government, there were failures of imagination, policy, capabilities, and management.[22]

Imagination

The most important failure was one of imagination. We do not believe leaders understood the gravity of the threat. The terrorist danger from Bin Laden and al Qaeda was not a major topic for policy debate among the public, the media, or in Congress. Indeed, it barely came up during the 2000 presidential campaign.

Al Qaeda's new brand of terrorism presented challenges to U.S. governmental institutions that they were not well-designed to meet. Though top officials all told us that they understood the danger, we believe there was uncertainty among them as to whether this was just a new and especially venomous version of the ordinary terrorist threat the United States had lived with for decades, or it was indeed radically new, posing a threat beyond any yet experienced.

As late as September 4, 2001, Richard Clarke, the White House staffer long responsible for counterterrorism policy coordination, asserted that the government had not yet made up its mind how to answer the question: "Is al Qaeda a big deal?"

A week later came the answer.

Terrorism was not the overriding national security concern for the U.S. government under either the Clinton or the pre-9/11 Bush administration.

The policy challenges were linked to this failure of imagination. Officials in both the Clinton and Bush administrations regarded a full U.S. invasion of Afghanistan as practically inconceivable before 9/11.

Capabilities

Before 9/11, the United States tried to solve the al Qaeda problem with the capabilities it had used in the last stages of the Cold War and its immediate aftermath. These capabilities were insufficient. Little was done to expand or reform them.

The CIA had minimal capacity to conduct paramilitary operations with its own personnel, and it did not seek a large-scale expansion of these capabilities before 9/11. The CIA also needed to improve its capability to collect intelligence from human agents.

At no point before 9/11 was the Department of Defense fully engaged in the mission of countering al Qaeda, even though this was perhaps the most dangerous foreign enemy threatening the United States.

America's homeland defenders faced outward. North American Aerospace Defense Command (NORAD) itself was barely able to retain any alert bases at all. Its planning scenarios occasionally considered the danger of hijacked aircraft being guided to American targets, but only aircraft that were coming from overseas.

The most serious weaknesses in agency capabilities were in the domestic arena. The FBI did not have the capability to link the collective knowledge of agents in the field to national priorities. Other domestic agencies deferred to the FBI.

FAA capabilities were weak. Any serious examination of the possibility of a suicide hijacking could have suggested changes to fix glaring vulnerabilities—expanding no-fly lists, searching passengers identified by the Computer Assisted Passenger Prescreening System (CAPPS) screening system, deploying federal air marshals domestically, hardening cockpit doors, alerting air crews to a different kind of hijacking possibility than they had been trained to expect. Yet the FAA did not adjust either its own training or training with NORAD to take account of threats other than those experienced in the past.

Management

The missed opportunities to thwart the 9/11 plot were also symptoms of a broader inability to adapt the way government manages problems to the new challenges of the twenty-first century. Action officers should have been able to draw on all available knowledge about al Qaeda in the government. Management should have ensured that information was shared and duties were clearly assigned across agencies, and across the foreign-domestic divide.

There were also broader management issues with respect to how top leaders set priorities and allocated resources.

For instance, on December 4, 1998, Director of Central Intelligence (DCI), Tenet issued a directive to several CIA officials and the Deputy Director of Central Intelligence (DDCI) for Community Management, stating: "We are at war. I want no resources or people spared in this effort, either inside CIA or the Community." The memorandum had little overall effect on mobilizing the CIA or the intelligence community. This episode indicates the limitations of the DCI's authority over the direction of the intelligence community, including agencies within the Department of Defense.

The U.S. government did not find a way of pooling intelligence and using it to guide the planning and assignment of responsibilities for joint operations involving entities as disparate as the CIA, the FBI, the State Department, the military, and the agencies involved in homeland security.

Intelligence Reform and Terrorism Prevention Act of 2004 (PL 108-458)

Many of the recommendations of the Final Report of the National Commission on Terrorist Attacks Upon the United States (The 9-11 Commission Report) were put into the Intelligence Reform and Terrorism Prevention Act of 2004. This Act, divided into 10 titles, brought about significant reorganization of intelligence community and critical infrastructures protection.[23]

Title I—Reform of the Intelligence Community

Special measures relating to the following subtitles were created:

A. Establishment of Director of National Intelligence

B. National Counterterrorism Center, National Counter Proliferation Center, and National Intelligence Centers

23. "Intelligence Reform and Terrorism Prevention Act of 2004," U.S. Senate Select Committee on Intelligence http://intelligence.senate.gov/laws/pl108-458.pdf (downloaded 10/20/2008).

C. Joint Intelligence Community Council
D. Improvement of education for the intelligence community
E. Additional improvements of intelligence activities
F. Privacy and civil liberties
G. Conforming and other amendments
H. Transfer, termination, transition, and other provisions
I. Other matters

Title II—Federal Bureau of Investigation

Improvement of intelligence capabilities of the Federal Bureau of Investigation

Title III—Security Clearances

Special measures relating to the security clearances have been created.

Title IV—Transportation Security

Special measures relating to the following subtitles were created:

A. National strategy for transportation security
B. Aviation security
C. Air cargo security
D. Maritime security
E. General provisions

Title V—Border Protection, Immigration, and Visa Matters

Special measures relating to the following subtitles were created:

A. Advanced Technology Northern Border Security Pilot Program
B. Border and immigration enforcement
C. Visa requirements
D. Immigration reform
E. Treatment of aliens who commit acts of torture, extrajudicial killings, or other atrocities abroad

Title VI—Terrorism Prevention

Special measures relating to the following subtitles were created:

A. Individual terrorists as agents of foreign powers
B. Money laundering and terrorist financing
C. Money laundering abatement and financial antiterrorism technical corrections
D. Additional enforcement tools
E. Criminal history background checks
F. Grand jury information sharing
G. Providing material support to terrorism
H. Stop Terrorist and Military Hoaxes Act of 2004
I. Weapons of Mass Destruction Prohibition Improvement Act of 2004
J. Prevention of Terrorist Access to Destructive Weapons K. Pretrial detention of terrorists

Title VII—Implementation of 9-11 Commission Recommendations

Special measures relating to the following subtitles were created:

A. Diplomacy, foreign aid, and the military in the war on terrorism
B. Terrorist travel and effective screening
C. National preparedness
D. Homeland security
E. Public safety spectrum
F. Presidential transition
G. Improving international standards and cooperation to fight terrorist financing
H. Emergency financial preparedness

Title VIII—Other Matters

Special measures relating to the following subtitles were created:

A. Intelligence matters
B. Department of homeland security matters
C. Homeland security civil rights and civil liberties protection

Implementing Recommendations of the 9-11 Commission Act of 2007 (PL 110-53)

Soon after the Democratic Party came into the majority in the House of Representatives, the 110th Congress passed another act, "Implementing Recommendations of the 9-11 Commission Act of 2007 (PL 110-53, August 3, 2007)."[24] Approximately a year after the passing of this law, the Majority Staffs of the Committees on Homeland and Foreign Affairs put its attention on the extent to which the law was indeed implemented and issued a report on "Wasted Lessons of 9/11: How The Bush Administration Ignored the Law and Squandered Its Opportunities to Make Our Country Safer."[25]

This comprehensive Homeland Security legislation included provisions to strengthen the nation's security against terrorism by requiring screening of all cargo placed on passenger aircraft; securing mass transit, rail and bus systems; assuring the scanning of all U.S.-bound maritime cargo; distributing Homeland Security grants based on risk; creating a dedicated grant program to improve interoperable radio communications; creating a coordinator for U.S. nonproliferation programs and improving international cooperation for interdiction of weapons of mass destruction; developing better mechanisms for modernizing education in Muslim communities and Muslim-majority countries, and creating a new forum for reform-minded members of those countries; formulating coherent strategies for key countries; establishing a common coalition approach on the treatment of detainees; and putting resources into making democratic reform an international

24. "Implementing Recommendations of the 9-11 Commission Act of 2007," The White House, www.whitehouse.gov/news/releases/2007/08/20070803-1.html (downloaded 10/24/2008).
25. "Wasted lessons of 9/11: How the bush administration ignored the law and squandered its opportunities to make our country safer," *The Gavel*, http://speaker.house.gov/blog/?p=1501 (downloaded 10/24/2008).

effort, rather than a unilaterally U.S. one. When President George W. Bush signed H.R. 1 into law on August 3, 2007 without any limiting statement, it seemed that the unfulfilled security recommendations of the 9-11 Commission would finally be implemented. To ensure that they were, over the past year the Majority staffs of the Committees on Homeland Security and Foreign Affairs have conducted extensive oversight to answer the question, *How is the Bush Administration doing on fulfilling the requirements of the "Implementing Recommendations of the 9-11 Commission Act of 2007 (P.L. 110-53)?* The Majority staffs of the two Committees prepared this report to summarize their findings. While the Majority staffs of the Committees found that the Bush Administration has taken some steps to carry out the provisions of the Act, this report focuses on the Administration's performance with respect to key statutory requirements in the following areas: (1) aviation security; (2) rail and public transportation security; (3) port security; (4) border security; (5) information sharing; (6) privacy and civil liberties; (7) emergency response; (8) biosurveillance; (9) private sector preparedness; and (10) national security. In each of the 25 individual assessments in this report, a status update is provided on the Bush Administration's performance on these key provisions. The status of the key provisions identified in the report, help explain why the report is entitled "Wasted Lessons of 9/11: How the Bush Administration Has Ignored the Law and Squandered Its Opportunities to Make Our Country Safer."[26]

Based on this report, it is clear that the Bush Administration did not deliver on myriad critical homeland and national security mandates set forth in the "Implementing the Recommendations of 9-11 Commission Act of 2007." Members of the Committees were alarmed that the Bush Administration did not make more progress on implementing these key provisions.,

wide-ranging recommendations to help prevent future terrorist attacks. Many of these recommendations were put in place with the passage of the "Intelligence Reform and Terrorism Prevention Act" and "Implementing Recommendations of the 9-11 Commission Act of 2007."

About a year after the passing of this law, the Majority Staffs of the Committees on Homeland and Foreign Affairs drew its attention on the extent to which the law was indeed implemented and issued a report on "Wasted Lessons of 9/11: How the Bush Administration Ignored the Law and Squandered Its Opportunities to Make Our Country Safer." This report demonstrates that it is clear that the Bush Administration did not deliver on myriad critical homeland and national security mandates set forth in the "Implementing the 9-11 Commission Recommendations Act of 2007." Fulfilling the unfinished business of the 9-11 Commission will most certainly be a major focus of President Obama, as many of the statutory requirements are to be met in stages.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The Public Health Security, Bioterrorism Preparedness & Response Act of 2002, authorizes funding for a wide range of public health initiatives.
2. True or False? The Homeland Security Act of 2002 establishes a new Executive Branch agency, the U.S. Department of Homeland Security (DHS), and consolidates the operations of 33 existing federal agencies.
3. True or False? The E-Government Act of 2012 establishes a Federal Chief Information Officers Council to oversee government information and services, and creation of a new Office of Electronic Government within the Office of Management and Budget.
4. True or False? Presidential directives are issued by the National Security Council and are signed or authorized by the Vice President.
5. True or False? The homeland security presidential directives called for deep and fundamental organizational changes to the executive branch of the government.

Multiple Choice

1. Faced with the challenge of strengthening the components to function as a unified Department, ________________ must coordinate centralized, integrated activities across components that are distinct in their missions and operations.
   A. Qualitative analysis
   B. Vulnerabilities
   C. Data storage
   D. Malformed request DoS
   E. DHS
2. There are various ____________ of The Department of Homeland Security that are involved with Information Technology Security.
   A. Network attached storage (NAS)
   B. Risk assessment

26. "Wasted lessons of 9/11: How the bush administration ignored the law and squandered its opportunities to make our country safer," *The Gavel*, http://speaker.house.gov/blog/?p=1501 (downloaded 10/24/2008)

C. Valid
D. Subcomponents
E. Bait

3. There are various ___________that support information sharing at the state and the federal levels.
   A. Organizations
   B. Fabric
   C. Disasters
   D. Risk communication
   E. Security
4. The Governor's Office of Homeland Security (OHS) acts as the ___________ for the prevention of and preparation for a potential terrorist event.
   A. Cabinet-level state office
   B. Greedy strategy
   C. Infrastructure failure
   D. SAN protocol
   E. Taps
5. The California Office of Information Security and Privacy Protection (OISPP) unites _________ with the oversight of government's responsible management of information.
   A. Irrelevant
   B. Consumer privacy protection
   C. IP storage access
   D. Configuration file
   E. Unusable

EXERCISE

Problem

Content Filtering

Pete Nicoletti, CISSP, CISA, CCSK
Director of Security Solutions and Compliance at Virtustream, Inc.

1. DEFINING THE PROBLEM

No one can deny that the Internet is one of the greatest inventions of the late 20th century. It has touched many aspects of our everyday lives including, how we communicate, how we conduct business, or simply how we entertain ourselves. While there are many legitimate uses for the Internet like, social networking, entertainment, and work, there are also some very serious risks, some of which include: spam, viruses, worms, Trojans, keystroke loggers, identity theft, and Internet scams. While these risks have the potential to impact us all, businesses today have some very unique risks when it comes to leveraging the power of the Internet:

- Loss of productivity
- Sensitive data loss through intentional and unintentional means
- Application performance issues caused by bandwidth intensive applications
- Infection and destruction of corporate information and computing resources due to increased exposure to Web-based threats such as viruses, worms, Trojans, spyware, etc.
- Legal liability when employees access/download inappropriate and offensive material such as pornography, racism, violence, etc.

Surfing the Web is the most common of all Internet activities. It offers global access to all types of information, banking, buying and selling goods and services from the comfort of our computer, and online bill paying, and it's so entertaining in many different ways. For business, access to Web apps is mission critical, and other sites are productivity tools. Accessing the Internet from the office is constantly presenting new challenges to manage. Some of the negative impacts of doing the wrong thing and going to the "wrong places" include:

- Lost productivity due to nonbusiness-related Internet use
- Higher costs as additional bandwidth is purchased to support legitimate and illegitimate business applications
- Network congestion; valuable bandwidth is being used for nonbusiness purposes, and legitimate business applications suffer
- Loss or exposure of confidential information through chat sites, nonapproved email systems, IM, peer-to-peer file sharing, etc.
- Infection and destruction of corporate information and computing resources due to increased exposure to Web-based threats (viruses, worms, Trojans, spyware, etc.) as employees surf nonbusiness-related Web sites.
- Legal liability when employees access/download inappropriate and offensive material (pornography, racism, etc.)
- Copyright infringement caused by employees downloading and/or distributing copyrighted material such as music, movies, etc.
- Negative publicity due to exposure of critical company information, legal action, and the like

Casual non-business relatad Web surfing has caused many businesses countless hours of lost productivity and occasionally hostile work environments have been created by employees who view and download offensive content. RIAA takedown notices and copyright infringement threats, fines, and lawsuits are increasing as employees use file-sharing programs to share their favorite music and movies. Government regulations and legal requirements are getting teeth with fines and penalties as company executives are being held accountable for their employees' actions. Corporate executives and IT professionals alike are now becoming more concerned about what their employees are viewing and downloading from the Internet. However, we are starting to see a paradigm shift with regards to how companies are choosing to leverage the power of the Internet, most importantly around brand recognition, advertising which often involve social media. There is a growing need to give employees access to the Internet as a business aide, thus ensuring the

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00093-3

safety of company assets is becoming increasingly difficult.

Government regulations on Internet access and information security are being enforced by many countries and individual states: the Children's Internet Protection Act (CIPA) for schools and libraries, Japan's Internet Association's SafetyOnline2 to promote Internet filtering, HIPAA, Sarbanes-Oxley, Gramm-Leach-Bliley, and "duty of care" legal obligation legislation are just a few. Many independent reports and government agencies (such as the FBI) are now reporting that employees are the single highest risk and are the most common cause of network abuse, data loss, and legal action. Because employers can be ultimately held responsible for their employees' actions, many businesses are now working aggressively with their Human Resources departments to define acceptable Internet usage. Reports of Internet abuse include:

- Global consulting firm IDC reports that 30–40% of Internet access is being used for nonbusiness purposes.
- The American Management Association reports that 27% of Fortune 500 companies have been involved in sexual harassment lawsuits over their employees' inappropriate use of email and Internet.
- The Center of Internet Studies have reported that more than 60% of companies have disciplined employees over Internet and email use, with more than 30% terminating employees.

  Numerous stories of employee dismissal, sexual harassment, and discipline with regard to Internet use can be found on the Internet[1]:
- The Recording Industry Association of America (RIAA) and the Motion Picture Association of America (MPAA) have relentlessly pursued legal action against schools, corporations, and individuals over the illegal downloading of music and movies from the Internet. The RIAA recently won a case against an Arizona company for $1 million.
- An oil and gas company recently paid $2.2 million to settle a lawsuit for tolerating a hostile work environment created by the downloading and sharing of Internet pornography.

To address these issues, companies are choosing to create Internet usage polices and develop education programs to train employees on how to safely use the Internet for browsing and communication in a manner that protects all parties from legal action and financial losses. To become compliant with many new policies and compliance regulations, corporations have chosen to start monitoring and controlling Web access. As companies are depending on the Internet for their businesses to flourish and cyber criminals are evolving and becoming increasingly more sophisticated, Web2.0 content filtering is becoming an essential part of every Internet and network security strategy.

2. WHY CONTENT FILTERING IS IMPORTANT

This section examines the motivating factors that each of the entities below consider when purchasing a content filtering solution:

- Schools and Libraries
- Commercial businesses
- Financial organizations
- Healthcare organizations
- Local, state, and federal government
- Parents

Each of the preceding faces different risks. But, they are all trying to solve one or more of the following challenges:

- Maintain compliance
- Protect company and client sensitive data (DLP: Data Leakage Prevention)
- Maximize employee productivity
- Avoid costly legal liabilities due to sexual harassment and hostile work environment lawsuits
- Preserve network and Internet resources
- Enforce company acceptable use policies (also known as Internet access policies)
- Control access to customer records and private data
- Monitor communications going into and out of a company
- Protect children

Let's look at the specific risks driving these entities to review their motivation to filter content.

Schools

In 2000, the United States Congress enacted the Children's Internet Protection Act (CIPA) to address concerns about children accessing harmful or obscene content over the Internet. This act imposes requirements on schools and libraries that receive discounts or funding for Internet access through the government's E-rate program. Schools and libraries may not receive E-rate assistance unless they can certify that they have an Internet safety

1. Stories of workers being dismissed for porn surfing: "IT manager fired for lunchtime Web surfing," www.theregister.co.uk/1999/06/16/it_manager_fired_for_lunchtime; "Xerox fires 40 in porn site clampdown," www.theregister.co.uk/2000/07/15/xerox_fires_40_in_porn; "41 District workers have been fired/suspended for visiting pornographic Web sites," www.wtopnews.com/?sid=1331641&nid=25.

policy that includes technology protection measures, which include blocking/filtering access to: (a) obscene content; (b) child pornography; or (c) anything harmful to minors, for all computers that are accessible by minors. For additional information on CIPA, please review http://www.fcc.gov/guides/childrens-internet-protection-act[2]

Why Content Filtering is Important

There are many reasons companies consider implementing content filtering, which can range from improving employee productivity, to blocking web based threats, and even prevent data leaks. In commercial businesses the motivations will vary based on the industry, any compliance or regulation that might be required, and the organization's culture. Many companies prefer to allow employees to access recreational content for a limited amount of time each day, this helps to strike a balance of maintaining employee productivity and employee morale.

Financial Organizations

Financial organizations have unique privacy and security concerns due to the fact that they need to protect their customer's personally identifiable information such as credit card numbers, Social Security numbers, and other financial related information which means they have no room for error. Data leakage is a very serious concern for financial institutions because an event can lead to financial losses, loss of reputation, competitive information, customers, and legal action. This risk tends to be the primary driver for financial institutions to consider content filtering and reporting on employees' Internet activity.

Healthcare Organizations

In today's fast-paced technological world, healthcare organizations must keep their costs and risks down. When employees inadvertently disclose sensitive information through intentional or unintentional means, it puts health organizations in financial and legal jeopardy. To help Healthcare organizations protect confidential patient information, The Department of Health and Human Services created the Health Insurance Portability and Accountability Act of 1996 (HIPAA). This act sets national standards for the protection of certain health information and outlines how medical records should be securely shared for legitimate purposes. HIPAA also requires that an audit log be kept for medical record access, which is one of the many reasons healthcare organizations implement content filtering.

2. Children's Internet Protection Act http://www.fcc.gov/guides/childrens-internet-protection-act

Internet Service Providers

ISPs have unique motivations with regards to content filtering. One of the primary reasons is, ISPs have to comply and produce logs in response to requests from law enforcement, including assisting the government with the USA PATRIOT Act and CIPA, and must have technology in place to monitor the activities of their customers.

U.S. Government

In the United States, the threat from websites that host malicious software presents a significant risk which can be easily managed through content filtering. In addition, the military is attempting to reduce the number of Internet connection points from thousands to hundreds, to reduce the risks we've described. National secrets, military plans, and information about soldiers and citizens cannot be exposed to our enemies by inadvertent surfing to the wrong places and downloading Trojans, keystroke loggers, or other types of malware. Additionally, logging is another key requirement that the U.S. Government leverages content filtering for; it provides classification of visited sites, which makes identifying trends and reading reports easier and more meaningful.

Other Governments

Other countries only allow their government employees access to whitelisted sites, to control access to news and other information that censors determine to be inappropriate. In Russia the ruling party routinely shuts off access to political rivals' Web sites. China has deployed and maintains a new and virtual "Great Firewall of China" (also known as the Golden Shield Project). Ministry of Public Security Authorities determine sites that they believe represent an ideological threat to the Chinese Communist Party and then prevent their citizenry surfing, blogging, and emailing to blocked sites with sophisticated content-filtering methods, including IP address blocking and even DNS cache poisoning. Russia, Tibet, North Korea, Australia, China, Iran, Cuba, Thailand, Saudi Arabia, and many other repressive governments use similar technology. The ironic part of these massive content-filtering efforts is that many U.S.-based technology companies have been involved in their construction, sometimes as a contingency for doing business in China or other censoring countries.[3]

3. U.S. companies' involvement in the "Golden Shield" Chinese content-filtering project, www.forbes.com/forbes/2006/0227/090.html, www.businessweek.com/magazine/content/06_08/b3972061.htm.

Libraries

The use of Internet filters or content-control software varies widely in public libraries in the United States, since Internet use policies are established by local library boards. As mentioned above, many libraries adopted Internet filters after Congress conditioned the receipt of universal service discounts with the use of Internet filters through the Children's Internet Protection Act (CIPA). Other libraries do not install content control software, believing that acceptable use policies and educational efforts address the issue of children accessing age-inappropriate content while preserving adult users' right to freely access information. Some libraries use Internet filters on computers used by children only. Some libraries that employ content-control software allow the software to be deactivated on a case-by-case basis, based on submitting an application to a librarian; libraries that are subject to CIPA are required to have a policy that allows adults to request that the filter be disabled without having to explain the reason for their request. Libraries have other legal challenges as well. In 1998, a U.S. federal district court in Virginia ruled that the imposition of mandatory filtering in a public library violates the First Amendment of the U.S. Bill of Rights.[4]

Parents

There are many ways parents can protect their children from inappropriate material on the Internet; and, web content filtering should be one of them. There are dozens of products for parents to consider when it comes to content filtering, as many browsers and consumer-grade endpoint security packages include a content filter, all with varying degrees of flexibility. Parents should research which solution will work best for their family based on children's age and whether or not the children are technology savvy. Additional features such as, a password based bypass, reporting, and parental alerting when an attempt to access blocked content is made, should also be considered before making a decision.

3. CONTENT CATEGORIZATION TECHNOLOGIES

There are many technologies that can be used to categorize content. Most commercial products use a number of techniques together to optimize their capability, and below is a list of some of the most popular techniques.

4. "Library content filtering is unconstitutional," Mainstream Loudon v. Board of Trustees of the Loudon County Library, 24 F. Supp. 2d 552 (E. D. Va. 1998).

Keyword Lists

The keyword lists method allows the creation of a blacklist dictionary that contains keywords or phrases. URLs and Web content are compared against the blacklist to block unauthorized Web sites. This technology relies on a manual update process, with vendors providing blacklists as starting points, requiring customers to manually update/tune the lists by adding or excluding keywords. Since updates are usually performed manually, filtering accuracy may be impacted due to the rate at which content changes and the fact that the Internet has progressed from a publishing model, to a community model with interactive content. This progression is making it difficult to rely on keyword lists as a primary tool. For example, if a user goes to the BBC sports site to lookup stats from the World Cup Soccer Tournament, their browser will make over 15 connections to servers in 6 domains possibly spanning multiple countries and languages. Simple keyword lists won't provide protection if one of those domains is compromised with malware or contains material that would be considered offensive While this feature is widely available in many commercial and freeware products today, it has largely been replaced with more advanced technologies such as Bayesian and reputation analysis.

URL Lists

URL lists contain full and/or partial URLs, which are compared to the URL in an HTTP get request. This technology is different from keyword lists because keyword lists look at content both within the HTML page and the URL, whereas URL lists just look at the address in the get request. However, URL lists tend to be a little more precise when looking to block a specific web site. One similarity between URL and keyword lists is that both are maintained through manual updates, which is why neither is used as primary technologies when categorizing content. The drawback to technologies that require manual updating is depending on the frequency of the updates, the lists may fall out of compliance with the corporate policy. While there are many uses for this specific technology, most organizations use URL lists to locally recategorize content that has been rated using another technology.

Content Categorization as a Service

The goal of organizing websites into categories based on the content in a web site is to make administration and updating of web filters easier and more accurate. By leveraging static categories, system administrators can simply choose which categories to block and which to

allow. This type of service is typically offered as part of a fee based subscription but there are some free services that are available as well. The key to picking which service to use should be based on cost, technology used to rate content, granularity of categories, and frequency of updates. Today, most web-filtering companies utilize multiple technologies to accurately rate content, some of which are proprietary. Below is a list of the most popular techniques:

- Keyword and pattern matching
- Multilanguage pattern matching
- Bayesian Analysis
- Anti-Virus and Anti-Malware tools
- Traffic patterns
- Content Based Image Filtering
- Domain registration and reputation (Whois)
- Counter intelligence (subscribing to proxy avoidance, and malware hosting lists)

Bayesian Filters

Particular word combinations and phrases have certain probabilities of occurring together on Web sites. For instance, the word "breast" can have a number of contexts depending on other words around it. The first could be cooking, as in Chicken Breast, second could be health as in Breast Cancer Awareness, and finally it could be porn. Bayesian Analysis, as it is used in web site content categorization, looks for patterns such as the words: breast, cooking, baking, seasoning, degrees, recipe. In this example the website would be classified as food related. While Bayesian analysis works well for this purpose there is a drawback which is it needs to be trained to recognize these patterns. To train the filter, the user or external "grader" must manually indicate whether a new web site is a porn site, cooking site or healthcare related site. Eventually, the filter will learn enough from the training process to make decisions on it's own and can continue to learn new word patterns without too much human tuning. Typically most fee based subscription services, such as the ones we will explore later in this chapter, have gone through the process of training their filters, so you won't have to.

Content Labeling

Content labeling is considered another form of content-control. The Internet Content Rating Association (ICRA), now part of the Family Online Safety Institute, developed a content rating system to self-regulate online content providers. Using an online questionnaire, a Webmaster describes the nature of their Web content. A small file is generated that contains a condensed, computer-readable digest of this description that can then be used by content-filtering software to block or allow that site.

ICRA labels are deployed in a couple of formats. These include the World Wide Web Consortium's Resource Description Framework (RDF) as well as Platform for Internet Content Selection (PICS) labels used by Microsoft's Internet Explorer Content Advisor.

ICRA labels are an example of self-policing and self-labeling. Similarly, in 2006 the Association of Sites Advocating Child Protection (ASACP) initiated the Restricted to Adults (RTA) self-labeling initiative. The RTA label, unlike ICRA labels, does not require a Webmaster to fill out a questionnaire or sign up to use. Like ICRA, the RTA label is free. Both labels are recognized by a wide variety of content-control software.

Content-Based Image Filtering (CBIF)

The latest in content-filtering technology is CBIF. All the text-based content-filtering methods use knowledge of a site and text matching to rate it's content. This technique makes it impossible to filter visual and audio media. Content-based image filtering may resolve this issue, as shown in Figure e66.1 below. The method consists of examining the image itself for flesh tone patterns, detecting objectionable material and then blocking the offending site.

Step 1: Skin Tone Filter

First the images are filtered for skin tones. The color of human skin is created by a combination of blood (red) and melanin (yellow, brown). These combinations restrict the range of hues that skin can possess (except for people from the planet Rigel 7). In addition, skin has very little texture. These facts allow us to ignore regions with high-amplitude variations and design a skin tone filter to separate images before they are analyzed.

Tip: Determine if the image contains large areas of skin color pixels.

Step 2: Analyze

Since we have already filtered the images for skin tones, any images that have very little skin tones will be accepted into the repository. The remaining images are then automatically segmented and their visual signatures are computed.

Tip: Automatically segment and compute a visual signature for the image.

Step 3: Compare

The visual signatures of the potentially objectionable images are then compared to a predetermined reference

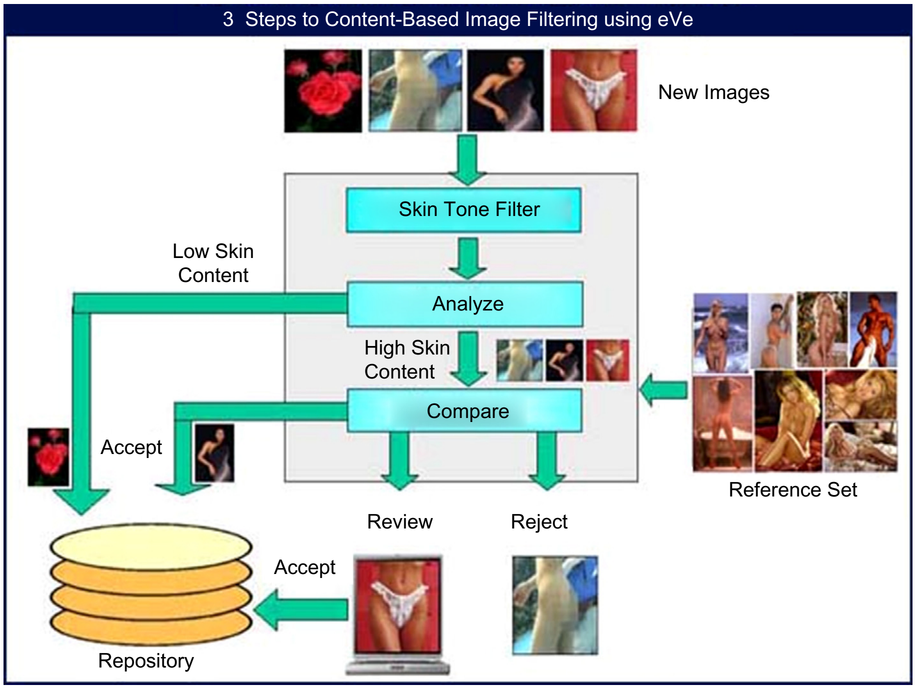

FIGURE e66.1 Content-based image filtering.

data set. If the new image matches any of the images in the reference set with over 70% similarity, the image is rejected. If the similarity falls in the range of 40–70%, that image is set aside for manual intervention. An operator can look at these images and decide to accept or reject them. Images that fall below 40% are accepted and added to the repository. These threshold values are arbitrary and are completely adjustable.[5]

Tip: Match the new image against a reference set of objectionable images and object regions.

4. PERIMETER HARDWARE AND SOFTWARE SOLUTIONS

There are several different technologies that help facilitate Web monitoring, logging, and filtering of HTTP, FTP sites, and other Web-related traffic. The methods available for monitoring and controlling Internet access range from manual to fully automated systems designed to scan, inspect, rate, and control Web activity in real-time.

Solutions can range from software that runs on Intel-based servers to purpose built appliances, like firewalls and proxies, that offer an administrator many different integration options. Two deployment options are inline and out-of-band, with each having their own benefits and risks, so it's very important to consider your deployment while deciding which solution to use.

Inline deployments are typically seen as the easiest from an installation perspective because you don't have to re-route traffic to the appliance, it's pretty much a drop in deployment. This design does tend to have some risks depending on the type of solution you decide to deploy. If the device is an application proxy, some applications might not function correctly which means you will have to spend time tweaking and bypassing non-proxy friendly traffic, which in a large network can be painful for users and time consuming for administrators. Please examine Table e66.1 for the risks and benefits of each deployment type.

Proxy Server vs. Firewall

There tends to be a lot of debate around which is device provides better security, a proxy server or a stateful network firewall. In early versions of both of these devices they served very different roles in network and Internet security. Early stateful firewalls operated at a much lower level in the OSI model than proxy servers do. The early firewall would allow and deny traffic based on OSI layers 3 and 4, and was great at performing this function. Proxy servers, sometimes called application proxies, are an intermediary between a client and a server operating at OSI layer 7, the application layer. This means that if a user Bob is sitting behind a proxy server that is connected to the Internet, and opens the browser on his workstation

5. Envision Search Technologies (permission to use), www.evisionglobal.com/index.html.

TABLE E66.1 Risks and Benefits of each Deployment Type.

	Benefits	Risk
Inline Deployment	• Visibility in to all Internet traffic • Easy to deploy • Easy to manage and troubleshoot	• Application compatibility issues • Single point of failure • Potential bottleneck • Limited scaling options for high availability • Requires outage to install
Out-of-band Deployment	• Forward only interesting traffic • Greater scalability and high availability options • Doesn't require network outage to install	• Often requires changes to network and/or client configurations - More difficult to deploy • Lack of visibility in to all Internet traffic • Difficult to troubleshoot

and requests a web page, his browser will ask the proxy server for that web page. The proxy server will then go out and get the page Bob requested from the Internet, maybe scan it for threats, make sure it's allowed, and send it over to Bob. The power of a proxy server is it can make decisions based on application layer data and even block granular functions within an application. As an example let's look at HTTP, an application proxy can determine if the traffic going over TCP port 80 is HTTP and if it's not, it can choose to block it. Going a little deeper, if someone attempted to tunnel Peer-to-Peer traffic over TCP port 80, they would not be able to get past an application proxy, but a firewall wouldn't be able to distinguish between these two applications because the firewall policy would likely allow TCP port 80 regardless of which application was using it. Another argument for using an application proxy is if you wanted to protect an application, such as a banking application, that was being published to the Internet, which is called a reverse proxy. A forward proxy requests resources from the Internet on behalf of users inside a LAN, and a reverse proxy services requests from the Internet and makes requests to a server or application sitting behind it; usually on a protected LAN or DMZ not allowed to connect directly to the Internet. Since a proxy server is an intermediary between a client and a server, it prevents a bank's customers, and more importantly hackers, from directly communicating with the server hosting the banking application. The administrators of the reverse proxy can choose to only allow certain HTTP methods, like the method GET, for most of the application's pages and only allow the method POST for pages or scripts that require use of that method. This allows a security administrator to mitigate some of the risk and gain greater control of Internet facing applications. There are many other benefits of using a proxy server that are outside the scope of this book and you should be familiar with them before deciding whether or not to use one. For all of the proxy's benefits, it's does have a number of limitations, such as it doesn't support a wide range of applications or protocols and they tend to require a lot of time and expertise to install not to mention ongoing administration. If they are not configured correctly and maintained regularly, the protection they provide can be greatly reduced and/or introduce issues in to the application that wouldn't otherwise be there.

The landscape changed when next-generation application firewalls became available to the market. Now, you could have a single device that had application awareness in addition to being a stateful firewall. The biggest difference between an application firewall and a proxy is an application firewall takes a client's original request and modifies the header, performs some inspections and if allowed, sends the original request to its destination. Whereas a proxy server will receive the request from the client, and initiate its own request to the destination to fulfill the client's request. Application firewalls quickly became a favorite of network administrators who were looking to protect their users while using the Internet and to protect applications that were published to the Internet. Since application firewalls have visibility all the way up to the application layer they can perform many of the functions that an application proxy does, like application validation, and content filtering.

Next-Generation firewalls (NGFW) are also known as UTM Appliances or Unified Threat Management Appliances. There are some people that consider these terminologies to be completely different; the fact is that UTM appliances are the same as NGFW as they both have many of the same features including application layer (OSI layer 7) firewall. While marketing departments are likely to blame for this confusion, you should consider them to be the same since they both describe the same type of technology and you should differentiate based on individual features that the various vendors offer. UTM appliances offer a wide range of services such as NGFW,

AV scanning, IPS/IDS, Web Filtering, and Application Control just to name a few.

Internet Gateway-Based Products/Unified Threat Appliances

One of the fastest-growing markets over the past several years has been the UTM appliance space, as shown in Figure e66.2. Let's review who the leaders are in both the UTM and Proxy markets. While there are many tools you can use to compare the products from the market leaders, like Gartner's Magic Quadrant, there is no replacement for a good old-fashioned proof of concept or "Bake-off" to determine which product will work best in your environment!

Fortinet

Fortinet's unique approach to protecting networks against the latest vulnerabilities involves several key security components. By combining many key security functions into one hardware platform called the FortiGate Multifunction Security Firewall, which benefits from their custom Application Specific Integrated Circuit (ASIC)

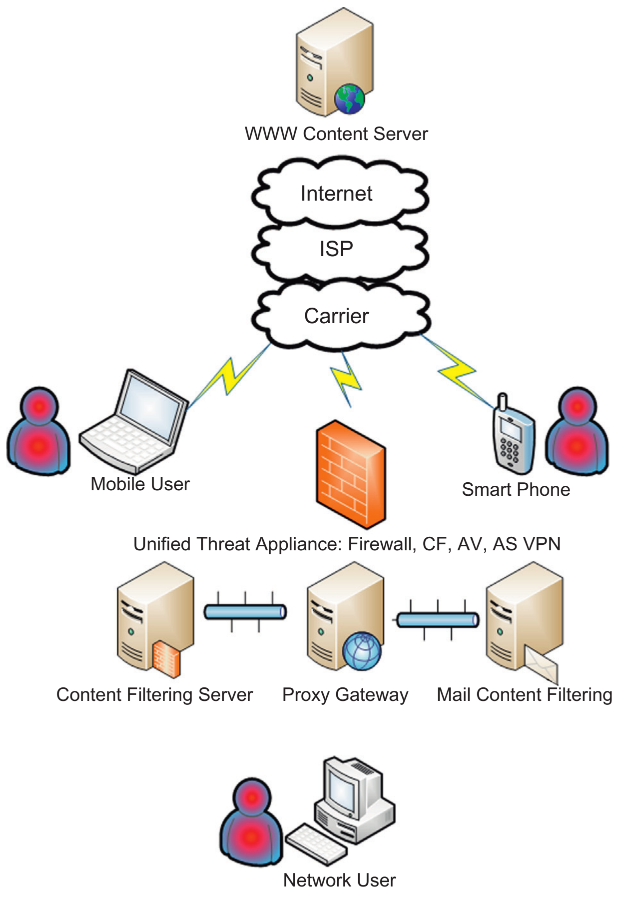

FIGURE e66.2 The UTM appliance space.

accelerated security processor, Fortinet has developed the world's first Dynamic Threat Prevention System. With this platform, Fortinet is able to quickly identify threats and proactively block them at the network level before they reach the endpoints to cause damage. Customers can create custom protection policies by turning on any of the security functions—Stateful Firewall, IPSec and SSL VPN, Antivirus, IDS & IPS, Web Content Filtering, Anti-Spam, and Bandwidth Shaping—in any combination and apply it to their traffic. Fortinet's Web Content Filtering technology allows customers to take a wide variety of actions to inspect, rate, and control Web traffic. Fortinet uses their own cloud-based service called FortiGuard for threat research, which provides web filtering, anti-virus, IPS, application control, etc., for all of their security platforms including their FortiGate Firewall.[6]

Websense

Websense started out as just a web filtering solution that would plug in to a customer's existing firewall infrastructure. They have always been known for great flexibility in deployment and perhaps the most granular category list, and for a long time were considered the leaders in reporting, for which they received numerous awards. Today, Websense is branching out to provide solutions in other growing areas of Internet security such as email protection, DLP, and mobile security, in addition to offering their own hardware appliances. While they may offer some similar features to UTM, they are not considered a UTM company since they don't offer firewall, which is a signature feature of UTM vendors.

Blue Coat

Blue Coat is widely considered the industry leader in Application Proxies. They started as a company that sold caching appliances to ISPs and large companies and built their security business around that product. Today they offer a cloud-based web filtering technology that works with their proxy platform and has recently introduced a total cloud-based service, which acts like a "proxy in the cloud" that users can access anywhere in the world from virtually any device. The benefit of the total cloud-based solution is it uses a subscription model, which doesn't require the customer to make a significant up-front investment in hardware. This new service allows smaller companies, that couldn't afford high-end content filtering, to leverage the same protection as larger companies. Blue Coat also offers solutions outside of their core web filtering and proxy products, which include anti-virus scanning, WAN optimization, traffic shaping and DLP. Their

6. Fortinet Multi-Threat Security Solution, www.fortinet.com/doc/whitepaper/Webfilter_applicationNote.pdf.

web filtering solution has a real-time feedback component where users' unrated URLs are automatically submitted to the cloud for real-time analysis, often receiving a real-time response. They have also connected their anti-virus appliance to their cloud, which provides real-time visibility in to sites that contain malware and they share this data amongst their customer base. There are many other companies including Secure Computing, Aladdin Knowledge Systems, Finjan, Marshal, FaceTime Communications, Webroot Software, Clearswift, CP Secure, IronPort Systems, ISS/IBM Proventia, Trend Micro, McAfee, MessageLabs, Barracuda Networks, ContentKeeper Technologies, Computer Associates, Cymphonix, Pearl Software, and St. Bernard, that all compete in the content filtering space each with their own unique features.

PC Based

PC software such as Norton Internet Security includes parental controls. Operating Systems such as Mac OS X and Microsoft's Windows Vista operating system also include content-control software. Other PC-based content-filtering software products are CyberPatrol, Cybersitter, EnoLogic NetFilter, iProtectYou Pro Web Filter, Net Nanny, Norton Internet Security, Safe Eyes Platinum, SentryPC, Bess, Crayon Crawler, Cyber Snoop, Covenant Eyes, K9 Web Protection, Naomi, Scieno Sitter, Sentry Parental Controls, Websense, Windows Live Family Safety, Windows Vista Parental Control, WinGate, X3Watch, and PlanetView. For the Apple users there are many options and the list is growing, some popular titles include Covenant Eyes, DansGuardian, Intego, and Mac OS X Parental Controls.

Remote corporate PCs and now the ever-increasing sophistication and capabilities of smart phones and tablets make them challenges for content-filtering deployments (see Figure e66.3). There are multiple ways to deal with these challenges one of which is to load a client on the device that provides local or cloud-based filtering, and VPNs with split tunneling disabled to force all traffic to go out the corporate protected Internet connection.

ISP-Based Solutions

Many ISPs offer parental control browser-based options, among them Charter Communications, EarthLink, Yahoo!, and AOL (see Figure e66.4). Cleanfeed is offered by British Telecom in the U.K. and is an ISP administered content-filtering system that targets child sexual abuse content using offensive image lists from the Internet Watch Foundation. Many ISPs in the US are starting to offer families a cloud-based content filtering solution for an additional monthly fee.

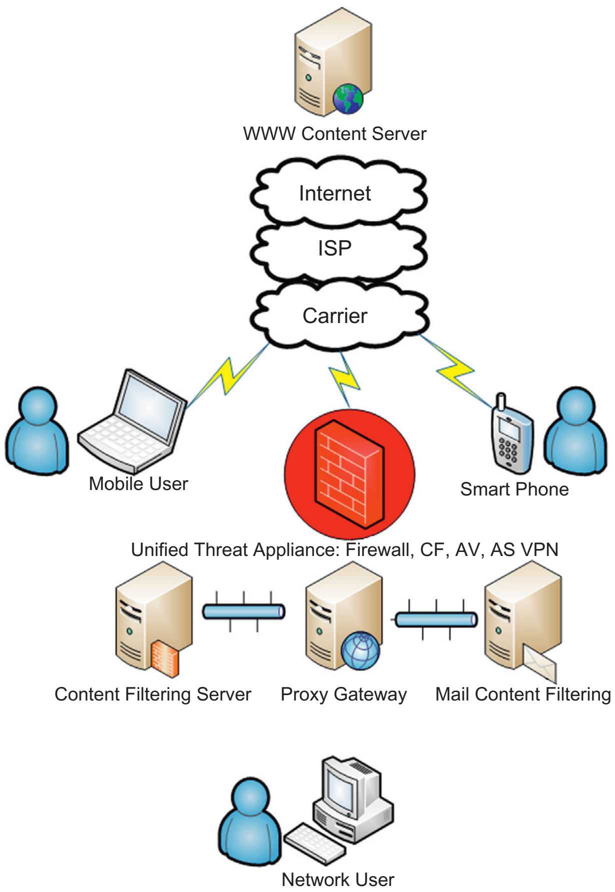

FIGURE e66.3 Content-filtering deployments.

Internet Based: Search Engine Safe Search

Safe Search is a feature that today is supported by most major search engines like Yahoo! and Google. Safe Search filters pornography from search engine results and can be toggled on or off in the browser. Most major content filtering companies have a feature to force it on regardless of the browser setting. In 2008 the Google search engine adapted a software program to faster track child pornography accessible through its site. The software is based on a pattern recognition engine. Content distribution networks that are attached to the Internet, such as Akamai, Limelight, Panther Express, EdgeCast, CDNetworks, Level 3, and Internap, manage the content in their networks and will not distribute offensive images (see Figure e66.5). In addition, some argue that using content-control software may violate Articles 13 and 17 of the Convention on the Rights of the Child.[7]

7. Convention on the Rights of the Child, www.unhchr.ch/html/menu3/b/k2crc.htm.

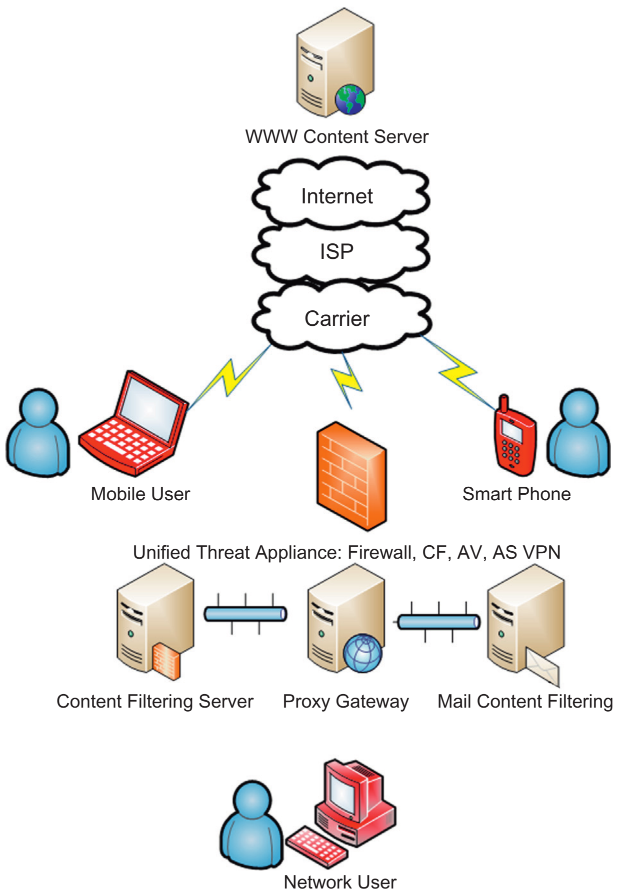

FIGURE e66.4 Many ISPs offer parental control browser-based options.

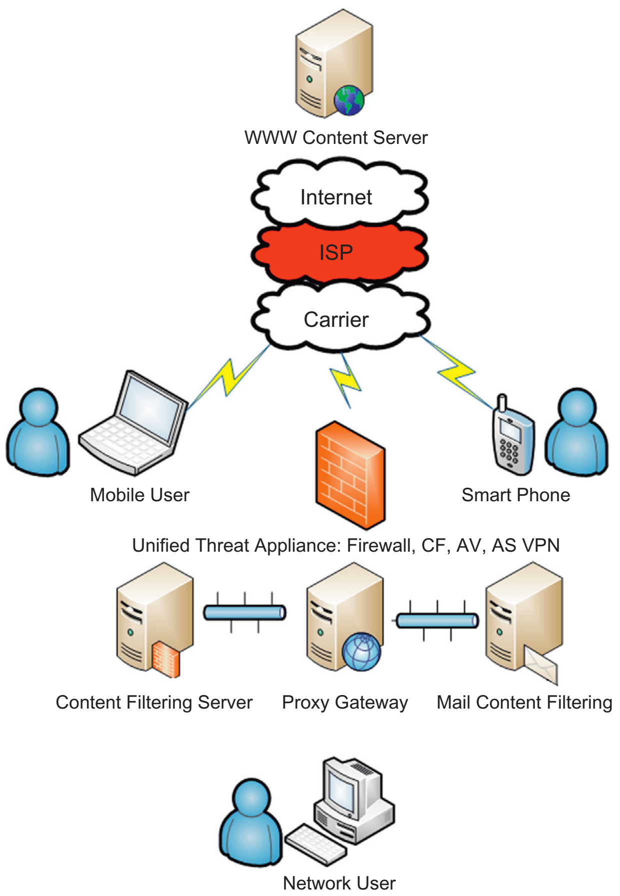

FIGURE e66.5 Content distribution networks that are attached to the Internet, such as Akamai, Limelight, Panther Express, EdgeCast, CDNetworks, Level 3, and Internap, manage the content in their networks and will not distribute offensive images.

5. CATEGORIES

It's tricky to determine the number of active web sites that are on the Internet today and due to its seemingly unstoppable growth, it will likely always remain difficult to determine an exact number. Most content-filtering companies have only rated a fraction of the entire Internet and do so using many different techniques that range from crawlers that attempt access every IP address to real-time services that examine URLs as users click on them. Social Media sites have traditionally been difficult to classify due to the broad range of services they offer. Many companies have chosen to apply multiple categories per URL that way they can distinguish between Social Networking: Games and Social Networking: Shopping and just Social Networking. It's important to consider how these sites are classified when choosing a solution because your corporate policy may be to allow social networking sites but deny games and shopping from both social networking sites and non-social networking sites (see checklist: "An Agenda For Action For Implementing Content-Control Filtering Software"). Table 66.2 below is the category list from Fortinet's Fortiguard service. Figure e66.6 shows the flow of categorization updates to the end user.

6. LEGAL ISSUES

There are many legal issues to consider in content filtering. And once you think you have a handle on your particular organizational requirements and have ensured that they are legal, a court will make a ruling that changes the game. A number of Internet technology issues and related challenges have not yet been fully addressed by legislatures or courts and are subject to a wide range of interpretation. For example, virtual child pornography, pornographic images and text delivered by SMS messages, sexual age-play in virtual game worlds, the soft porn Manga genre of Lolicon and Rorikon are all challenges to current laws and issues that will need to be addressed as our society comes to grips with the Internet

TABLE 66.2 79 Categories are Organized into the following 6 Main Groups.

General Interest - Business	Armed Forces, Business, Finance and Banking, General Organizations, Government and Legal Organizations, Information and Computer Security, Information Technology, Search Engines and Portals, Secure Websites, Web Hosting, Web-based Applications
General Interest - Personal	Advertising, Arts and Culture, Brokerage and Trading, Child Education, Content Servers, Digital Postcards, Domain Parking, Dynamic Content, Education, Entertainment, Folklore, Games, Global Religion, Health and Wellness, Instant Messaging, Job Search, Medicine, Meaningless Content, News and Media, Newsgroups and Message Boards, Personal Privacy, Personal Vehicles, Personal Websites and Blogs, Political Organizations, Real Estate, Reference, Restaurants and Dining, Shopping and Auction, Social Networking, Society and Lifestyles, Sports, Travel, Web Chat, Web-based Email
Bandwidth Consuming	File Sharing and Storage, Freeware and Software Downloads, Internet Radio and TV, Internet Telephony, Peer-to-Peer File Sharing, Streaming Media and Downloads
Controversial	Abortion, Adult Materials, Advocacy Groups, Alcohol, Alternative Beliefs, Dating, Extremist Groups, Gambling, Lingerie and Swimsuit, Marijuana, Nudity and Risque, Pornography, Sex Education, Sport Hunting and War Games, Tobacco, Weapons
Potentially Liable	Child Abuse, Discrimination, Drug Abuse, Hacking, Illegal or Unethical, Plagiarism, Proxy Avoidance, Violence
Security Risk	Malicious Websites, Phishing, Spam URLs

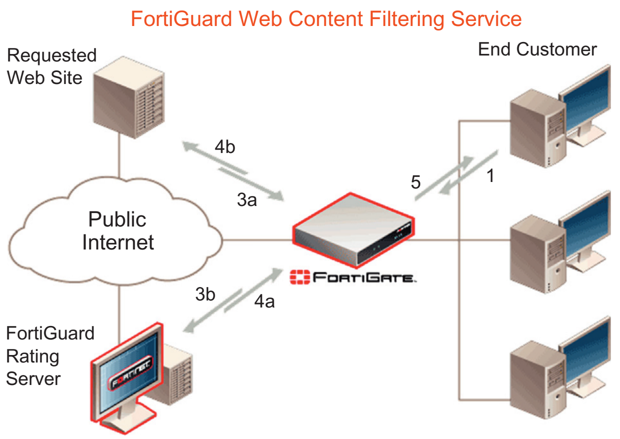

FIGURE e66.6 The flow of categorization updates to the end user.

and what is "out there." The following discussion centers on the most relevant laws in the content-filtering space.

Federal Law: ECPA

The Electronic Communications Privacy Act (ECPA)[8] allows companies to monitor employees' communications when one of three provisions are met: one of the parties has given consent, there is a legitimate business reason, or the company needs to protect itself.

8. U.S. Code: Wire and Electronic Communications Interception and Interception of Oral Communications, www.law.cornell.edu/uscode/18/usc_sup_01_18_10_I_20_119.html.

If your company has no content access policy in place, an employee could argue that he or she had a reasonable expectation of privacy. However, if the company has implemented a written policy whereby employees are informed about the possibility of Web site monitoring and warned that they should not have an expectation of privacy, the company is protected from this type of privacy claim.

CIPA: The Children's Internet Protection Act

CIPA provisions have both the "carrot and the stick." The U.S. government will pay you for equipment to access the Internet, but you have to play by its rules to get the money! Having been rebuffed by the courts in its previous efforts to protect children by regulating speech on the Internet, Congress took a new approach with the Children's Internet Protection Act (CIPA). See, for example *Reno v. ACLU*, 521 U.S. 844 (1997) (overturning the Communications Decency Act of 1996 on First Amendment grounds). With CIPA, Congress sought to condition federal funding for schools and libraries on the installation of filtering software on Internet-ready computers to block objectionable content.

CIPA is a federal law enacted by Congress in December 2000 to address concerns about access to offensive content over the Internet on school and library computers. CIPA imposes certain types of requirements on any school or library that receives funding for Internet access or internal connections from the E-rate program, which makes certain communications technology more affordable for eligible schools and libraries. In early

An Agenda for Action for Implementing Content-Control Filtering Software

Social networking sites and non-social networking sites are organized into between 10 and 90 various categories. Typical subjects of content-control software include (Check All Tasks Completed):

_____**1.** Illegal content with reference to the legal domain being served by that company.

_____**2.** Promote, enable, or discuss system cracking, software piracy, criminal skills, or other potentially illegal acts.

_____**3.** Sexually explicit content, such as pornography, erotica, nudity, and erotic discussions of sexual topics such as sexuality or sex. Promote, enable, or discuss promiscuity, lesbian, gay, bisexual, transsexual, sexual activity outside of marriage, or other lifestyles seen to be immoral or alternative.

_____**4.** Contain violence or other forms of graphic or "extreme" content.

_____**5.** Promote, enable, or discuss bigotry or hate speech.

_____**6.** Promote, enable, or discuss gambling, recreational drug use, alcohol, or other activities frequently considered to be vice.

_____**7.** Are unlikely to be related to a student's studies, an employee's job function, or other tasks for which the computer in question may be intended, especially if they are likely to involve heavy bandwidth consumption.

_____**8.** Are contrary to the interests of the authority in question, such as Web sites promoting organized labor or criticizing a particular company or industry.

_____**9.** Promote or discuss politics, religion, health or other topics.

_____**10.** Prevent people who are hypochondriacs from viewing Web sites related to health concerns.

_____**11.** Include social networking opportunities that might expose children to predators.

_____**12.** Potentially liable: drug abuse, folklore, hacking, illegal or unethical, marijuana, occult, phishing, plagiarism, proxy avoidance, racism and hate, violence, Web translation.

_____**13.** Controversial: abortion, adult materials, advocacy groups/organizations, alcohol, extremist groups, gambling, lingerie and swimwear, nudity, pornography, sex education, sport hunting and war games, tasteless, tobacco, weapons.

_____**14.** Potentially nonproductive: Advertising, brokerage and trading, digital postcards, freeware, downloads, games, instant messaging, newsgroups and message boards, Web chat, Web-based email.

_____**15.** Potentially bandwidth consuming: Internet radio and TV, Internet telephony, multimedia download, peer-to-peer file sharing, personal storage.

_____**16.** Potential security risks: Malware, spyware.

_____**17.** General interest: Arts and entertainment, child education, culture, education, finance and banking, general organizations, health and wellness, homosexuality, job search, medicine, news and media, personal relationships, personal vehicles, personal Web sites, political organizations, real estate, reference, religion, restaurants and dining, search engines, shopping and auction, society and lifestyles, sports, travel.

_____**18.** Business oriented: Armed forces, business, government and legal organizations, information technology, information/computer security

_____**19.** Others: Content servers, dynamic content, miscellaneous, secure Web sites, Web hosting.

2001, the FCC issued rules implementing CIPA. CIPA made amendments to three federal funding programs: (1) the Elementary and Secondary Education Act of 1965, which provides aid to elementary and secondary schools; (2) the Library Services Technology Act, which provides grants to states for support of libraries; and (3) the E-Rate Program, under the Communications Act of 1934, which provides Internet and telecommunications subsidies to schools and libraries. The following are what CIPA requires[9] :

- Schools and libraries subject to CIPA may not receive the discounts offered by the E-Rate Program unless they certify that they have an Internet safety policy and technology protection measures in place. An Internet safety policy must include technology protection measures to block or filter Internet access to pictures that (a) are obscene, (b) are child pornography, or (c) are harmful to minors (for computers that are accessed by minors).
- Schools subject to CIPA are required to adopt and enforce a policy to monitor online activities of minors.
- Schools and libraries subject to CIPA are required to adopt and implement a policy addressing: (a) access by minors to inappropriate matter on the Internet; (b) the safety and security of minors when using electronic mail, chat rooms, and other forms of direct electronic communications; (c) unauthorized access, including so-called "hacking," and other unlawful activities by minors online; (d) unauthorized

9. What CIPA Requires, www.fcc.gov/cgb/consumerfacts/cipa.html.

disclosure, use, and dissemination of personal information regarding minors; and (e) restricting minors' access to materials harmful to them. Schools and libraries are required to certify that they have their safety policies and technology in place before receiving E-Rate funding, as follows:

- CIPA does not affect E-Rate funding for schools and libraries receiving discounts only for telecommunications, such as telephone service.
- An authorized person may disable the blocking or filtering measure during any use by an adult to enable access for bona fide research or other lawful purposes.
- CIPA does not require the tracking of Internet use by minors or adults.

"Harmful to minors" is defined under the *Act as: Any picture, image, graphic image file, or other visual depiction that (i) taken as a whole and with respect to minors, appeals to a prurient interest in nudity, sex, or excretion; (ii) depicts, describes, or represents, in a patently offensive way with respect to what is suitable for minors, an actual or simulated sexual act or sexual contact, actual or simulated normal or perverted sexual acts, or a lewd exhibition of the genitals; and (iii) taken as a whole, lacks serious literary, artistic, political, or scientific value as to minors.*

Court Rulings: CIPA from Internet Law Treatise

On June 23, 2003, the U.S. Supreme Court reversed a District Court's holding in *United States v. American Library Ass'n*, 539 U.S. 194 (2003).[10] It held that the use of Internet filtering software does not violate library patrons' First Amendment rights. Therefore, CIPA is constitutional and a valid exercise of Congress's spending power.

The Court held, in a plurality opinion, that libraries' filtering of Internet material should be subject to a rational basis review, not strict scrutiny. It explained that, because collective decisions regarding printed material have generally only been subject to a rational basis review, decisions regarding which Web sites to block should likewise be subject to the same test. It reasoned that libraries are no less entitled to make content-based judgments about their collections when they collect material from the Internet than when they collect material from any other source.

Further, it reasoned that heightened judicial scrutiny is also inappropriate because "Internet access in public libraries is neither a 'traditional' nor a 'designated' public forum" *(Id.* at 2304). Therefore, although filtering software may overblock constitutionally-protected speech and a less restrictive alternative may exist, because the government is not required to use the least restrictive means under a rational basis review, CIPA is nonetheless constitutional.

Moreover, the Court held that Congress did not exceed its spending power by enacting CIPA because, when the government uses public funds to establish a program, it is entitled to define its limits. By denying federal funding, the government is not penalizing libraries that refuse to filter the Internet, or denying their rights to provide their patrons with unfiltered Internet access. Rather, it "simply reflects Congress' decision not to subsidize their doing so"(*Id*. at 2308).[11]

The Trump Card of Content Filtering: The "National Security Letter"

The FBI, CIA, or DoD can issue an administrative subpoena to ISPs for Web site access logs, records, and connection logs for various individuals. Along with a gag order, this letter comes with no judicial oversight and does not require probable cause. In 2001, Section 505 of the PATRIOT Act powers were expanded for the use of the NSL. There are many contentious issues with these laws, and the Electronic Frontier Foundation and the American Civil Liberties Union (ACLU) are battling our government to prevent their expansion and open interpretation.[12]

State of Texas: An Example of an Enhanced Content-Filtering Law

Texas state law requires all Texas ISPs to link to blocking and filtering software sites. In 1997, during the 75th Regular Session of the Texas Legislature, House Bill 1300 was passed. HB 1300 requires ISPs to make a link available on their first Web page that leads to Internet "censorware" software, also known as "automatic" blocking and screening software. The two most important portions of the law are shown here:

Sec. 35.102. SOFTWARE OR SERVICES THAT RESTRICT ACCESS TO CERTAIN MATERIAL ON INTERNET.

(a) A person who provides an interactive computer service to another person for a fee shall provide free of charge to each subscriber of the service in this state a link leading to fully functional shareware, freeware, or demonstration versions of software or to a service that, for at least one operating system,

10. CIPA and E-Rate Ruling, www.cdt.org/speech/cipa/030623decision.pdf.

11. IETF Fights CIPA, http://ilt.eff.org/index.php/Speech:_CIPA.

12. ACLU Sues Over Internet Privacy, Challenges ISPs Being Forced to Secretly Turn Over Customer Data, www.cbsnews.com/stories/2004/04/29/terror/main614638.shtml.

enables the subscriber to automatically block or screen material on the Internet.

(b) A provider is considered to be in compliance with this section if the provider places, on the provider's first page of world wide Web text information accessible to a subscriber, a link leading to the software or a service described by Subsection (a). The identity of the link or other on-screen depiction of the link must appear set out from surrounding written or graphical material so as to be conspicuous.

Sec. 35.103. CIVIL PENALTY.

(a) A person is liable to the state for a civil penalty of $2,000 for each day on which the person provides an interactive computer service for a fee but fails to provide a link to software or a service as required by Section 35.102. The aggregate civil penalty may not exceed $60,000.[13]

(b) The attorney general may institute a suit to recover the civil penalty. Before filing suit, the attorney general shall give the person notice of the person's noncompliance and liability for a civil penalty. If the person complies with the requirements of Section 35.102 not later than the 30th day after the date of the notice, the violation is considered cured and the person is not liable for the civil penalty.

The following are international laws involving content filtering:

- UK: Data Protection Act
- EU: Safer Internet Action Plan
- Many other countries have also enacted legislation

Additionally, the United Kingdom and some other European countries have data retention policies. Under these policies ISPs and carriers are obliged to retain a record of all their clients' Web browsing. The data retention period varies from six months to three years. In the U.K. this retained data is available to a very wide range of public bodies, including the police and security services. Anyone who operates a proxy service of any kind in one of these countries needs to be aware that a record is kept of all Web browsing through their computers. On March 15, 2006, the European Union adopted Directive 2006/24/EC, which requires all member states to introduce statutory data retention. The United States does not have a statutory data retention specifically targeting information in this area, though such provisions are under consideration.

7. CIRCUMVENTING CONTENT FILTERING

Shortly after the first content filter was deployed, an industrious user found a way to bypass it. This next section will be highlighting a few things most people try, but should in no way be considered an exhaustive guide to preventing circumvention. For most of us, the goal shouldn't be to uncover every single circumvention method, but take care of the low hanging fruit. Another way to look at it is to make it hard enough for the common user to give up and don't worry about the über-technical person because the method they find will likely be too hard for the common person to figure out, even with instructions.

Circumvention Technologies

When it comes to circumvention, remember one thing, the user looking to get around your filter needs to get lucky once. You on the other hand to stop them, need to be lucky all the time. See how the cards are stacked against you? There are many ways to bypass a content filter; in fact there are commercial products and services that will help you do it. There are two primary ways to bypass content filtering and they are, using a proxy or tunneling the traffic through another protocol.

Tip: There are a few simple steps that administrators can take that will make it extremely difficult for users to bypass their content filters. First, require administrative access to install software on company owned machines, and manage software through a software management and distribution tool. Second, love your logs... There is so much valuable information that can be found in logs and all security devices worth buying will generate access logs.

Proxies

The first method we will explore is a proxy. There are basically five types of proxies:

- Client-based proxies
- Open proxies
- HTTP Web-based proxies
- Secure public and private Web-based proxies
- Secure anonymous Web-based proxies

Client-Based Proxies and Tunneling

These are programs that users download and run on their computers. Many of these programs are run as "portable applications," which means they don't require any installation or elevated privileges, so they can be run from a USB thumb drive by a user with limited privileges. The three most widely used include TorPark, which uses Firefox and the XeroBank network, Google Web Accelerator, and McAfee's Anonymizer.

These programs create a local proxy server using a nonstandard port. Then they configure the browser to use

13. Texas ISP Laws can be found here: www.tlc.state.tx.us/legal/b&ccode/b&c_title10/80C258(3).HTML

the local proxy by changing its proxy server settings to the form localhost:port = 127.0.0.1:9777, for example. Web content requests are then tunneled through the proxy program to an appropriate proxy server using a custom protocol, which is typically encrypted. The content-filtering gateway doesn't see the browser-to-local proxy traffic, because it flies under its content inspection radar. All the gateway may see is the custom protocol that encapsulates the user's Web request.

The network of proxy servers is either static, as is the case with commercial programs such as McAfee's Anonymizer and Google Web Accelerator, or it's private and dynamic, as is the case with Psiphon and XeroBank. In both cases, the proxy server network is typically built by individuals who volunteer their home computers for use by installing the corresponding proxy server software.

There are multiple ways to identify and block this circumvention method. One simple way is through examining firewall logs. The firewall will show unusual amounts of activity on non-standard ports, which is an easy way to identify this type of circumvention.

Currently the UltraSurf proxy client is the most advanced tool available to circumvent gateway security Web content filters. UltraSurf was developed by an organization called UltraReach,[14] which was founded by a group of Chinese political dissidents. UltraReach developers continue to actively maintain and update UltraSurf. They designed UltraSurf specifically to allow Chinese citizens to circumvent the Chinese government's efforts to restrict Internet use in China. The UltraSurf application is a very sophisticated piece of software. It uses a distributed network of proxy servers, installed and maintained by volunteers around the world, much like a peer-to-peer network. It uses multiple schemes to locate the proxy servers in its network, spanning different protocols. It uses port and protocol tunneling to trick security devices into ignoring it or mishandling it. It also uses encryption and misdirection to thwart efforts to investigate how it works.

Ultrasurf is free and requires no registration, which makes it widely distributable. It requires no installation and can be run by a user who doesn't have administrative permissions to his computer, which makes it very portable. It can easily be carried around on a USB thumb drive and run from there.

Another formidable bypass application is Psiphon.[15] This is a distributed "personal trust" style Web proxy designed to help Internet users affected by Internet censorship securely bypass content-filtering systems typically set up by governments. Psiphon was developed by the Citizen Lab at the University of Toronto, building on previous generations of Web proxy software systems. Psiphon's recommended use is among private, trusted relationships that span censored and uncensored locations (such as those that exist among friends and family members, for example) rather than as an open public proxy. Traffic between clients and servers in the Psiphon system is encrypted using the HTTPS protocol.

According to Nart Villeneuve, director of technical research at the Citizen Lab, "The idea is to get them to install this on their computer, and then deliver the location of that circumventor, to people in filtered countries by the means they know to be the most secure. What we're trying to build is a network of trust among people who know each other, rather than a large tech network that people can just tap into."

Psiphon takes a different approach to censorship circumvention than other tools used for such purposes, such as The Onion Router, aka Tor. Psiphon requires no download on the client side and thus offers ease of use for the end user. But unlike Tor, Psiphon is not an anonymizer; the server logs all the client's surfing history. Psiphon differs from previous approaches in that the users themselves have access to server software. The developers of Psiphon have provided the user with a Microsoft Windows platform executable for the Psiphon server. If the server software attains a high level of use, this would result in a greater number of servers being online. A great number of servers online would make the task of attacking the overall user base more difficult for those hostile to use of the Psiphon proxy than attacking a few centralized servers, because each individual Web proxy would have to be disabled one by one.

There are inherent security risks in approaches such as Psiphon, specifically those presented by logging by the services themselves. The real-world risk of log keeping was illustrated by the turnover of the emails of Li Zhi to the Chinese government by Yahoo. Li was subsequently arrested, convicted, and sent to jail for eight years.[16] Some have raised concerns that the IP addresses and the Psiphon software download logs of Psiphon users could fall into the wrong hands if the Citizen Lab computers were to get hacked or otherwise compromised.

These tools are a double-edged sword: They are incredibly powerful tools for allowing political dissidents around the world to evade oppression, but they also provide end users on private, filtered networks with a way to access the Internet that violates acceptable use policies and introduces liability to an organization. One way to block these types of circumventing technologies is by

14. UltraReach Information can be found at www.ultrareach.com/.

15. Psiphon: http://psiphon.civisec.org/. and servers in the Psiphon system is encrypted using the HTTPS protocol. https://s3.amazonaws.com/8qep-lrim-kctj/en.html

16. Yahoo may have helped jail another Chinese user, www.infoworld.com/article/06/02/09/75208_HNyahoohelpedjail_1.html.

using deep packet inspection to identify these applications and block their access.

Open "Explicit" Proxies

Open proxies are services that are offered online and can be accessed by changing the configuration of your browser. Your browser can be modified to send all traffic to a proxy at a specific IP and port. Some organizations deploy their own explicit proxy to enforce content filtering, in which case the browser will already be configured to use a proxy. To locate the proxy settings using Internet Explorer, go to Tools | Internet Options | Connections | LAN Settings. When a proxy is defined in the browser it is called an explicit proxy, because you are explicitly telling the browser where to send your web traffic. Depending on the configuration of your operating system, it may require you to have administrative privileges to change this setting.

When your PC is configured to use an open proxy, the browser simply sends all its Web content requests to the proxy, as opposed to resolving the URL to an IP and sending the request directly to the destination Web site. The open proxy then does the DNS name resolution, connects to the destination Web site, and returns that content to the browser.

There are multiple ways to identify and block this circumvention method. Firewall logs showing unusual amounts of access on non-standard ports could be an easy indicator that someone is using an explicit proxy service. Restricting access to browser settings without administrative access is a great way to prevent someone from using an explicit proxy, which needs to be coupled with restricting users ability to install software. Finally, if you are using a proxy server yourself consider denying clients direct access to the Internet. Remember your proxy will facilitate the clients' requests so if this option is a possibility, you may only need to give your proxy server access to the Internet.

HTTP Web-Based Proxies (Public and Private)

These are Web sites that are purpose-built to proxy Web traffic. They are very simple to use because a user just browses to the "proxy" web site, and types a URL in to a text box on the site. The proxy web site will then display the content from the URL that was submitted. The content inspection gateway only sees traffic to the proxy site.

PHProxy and CGIProxy are the most well-known development efforts used for this purpose. Peacefire's Circumventor is an example of an application using these tools kits. The HTML code request and response from the proxy is specifically engineered to evade filtering. The more difficult it is to reverse engineer the URL of the proxied site from the HTTP traffic that's flowing between the browser and the proxy, the more successful this method of circumvention is.

The biggest benefit for these types of proxies for the circumventer is that they are simple to install on your home or office computer. A nontechnical user can do it in a matter of minutes. Once it is installed, the user has a Web-based proxy running on his home computer, which is presumably not filtered. He can then access his home computer from a filtered network (like an office or school network) using just a browser, and circumvent your carefully crafted Web filtering policy.

At first glance it may seem difficult to detect this type of circumvention, but it's actually pretty easy. In fact, since this is likely accessed through your content filtering gateway there will be a record of these transactions, however it is very unlikely that your content filtering company would have rated this site. Examining your access logs for sites with an "unknown rating" can be a very easy clue that someone has created their own proxy. Additionally, most content filtering companies have a category for proxy avoidance, which should be blocked as a best practice.

Secure Public Web-Based Proxies

These proxies are basically the same as the HTTP Web-based proxies except that they use the SSL encrypted HTTPS protocol. There are two types of HTTPS proxies: public and anonymous. Public HTTPS proxies are built by organizations such as Proxy.org and Peacefire and are publicized via mailing lists and word of mouth. They intentionally look like completely legitimate sites, with properly constructed certificates that have been issued by trusted certificate authorities like VeriSign. These sites can be easily blocked today by using a gateway device that has the ability to intercept SSL traffic and blocking the proxy avoidance category. Additionally, looking for unrated https sites can indicate a user has created a secure version of the home proxy.

There is real risk when using Internet based proxies and some companies choose to explain these risks to users before they consider using this type of tool. There are nefarious individuals on the Internet who build open proxies and publicize them through mailing lists and message boards, etc.. Often they are built with criminal intent, as a way to steal user credentials. An open proxy can see, capture and log everything you are sending and receiving, even HTTPS. Explaining this risk to the end user may be enough to keep them from exploring it on their own.

Process Killing

Some of the more poorly designed PC installed content-filtering applications can be shut down by killing their processes. For example, that would include Microsoft Windows through the Windows Task Manager or in Mac OS using Activity Monitor.

Remote PC Control Applications

Another form of tunneling is to use: Windows RPC, VNC, Citrix GoToMyPc, BeAnywhere, WallCooler, I'm InTouch, eBLVD, BeamYourScreen, PCMobilizr, and Cisco's WebEx to browse the Internet from another machine. Some of these applications are business critical and will not be blocked by corporately deployed content-filtering systems, and their intentional misuse can be a serious risk.

8. ADDITIONAL ITEMS TO CONSIDER: OVERBLOCKING AND UNDERBLOCKING

Overblocking occurs when the content-filtering technology blocks legitimate Web sites that don't violate policy. Underblocking occurs when a content filter doesn't identify content that should be blocked.

Casual Surfing Mistake

A friend sends a link in email, a popup window offers up something interesting, or you mistype a Web site address and get a typo-squatter porn site. All these ways will land you on a Web site that is not approved by your content-filtering system. You better have a way to deal with this reality.

Getting the List Updated

Most content-filtering companies send out very frequent updates or offer real-time access. These must be accessed, downloaded, and incorporated. Scheduled checks should be done to ensure these updates are happening on a regular basis to avoid out of date information. Figure e66.7 below shows the flow of web site categorization and distribution of the updated lists to clients.

Override Authorization Methods

Many content filters have an option that allows authorized people to bypass the content filter. This is especially useful in environments where the computer is being supervised and the content filter is aggressively blocking Web sites that need to be accessed. Usually the company owners and executives claim this privilege.

Warn and Allow Methods

This option allows for the company to state its policy on browsing to certain categories or web sites, but ultimately leaves the decision to continue on to the site to the user. An example is shopping, many companies will warn users that personal shopping during business is a violation of company policy, but if the user is shopping for business

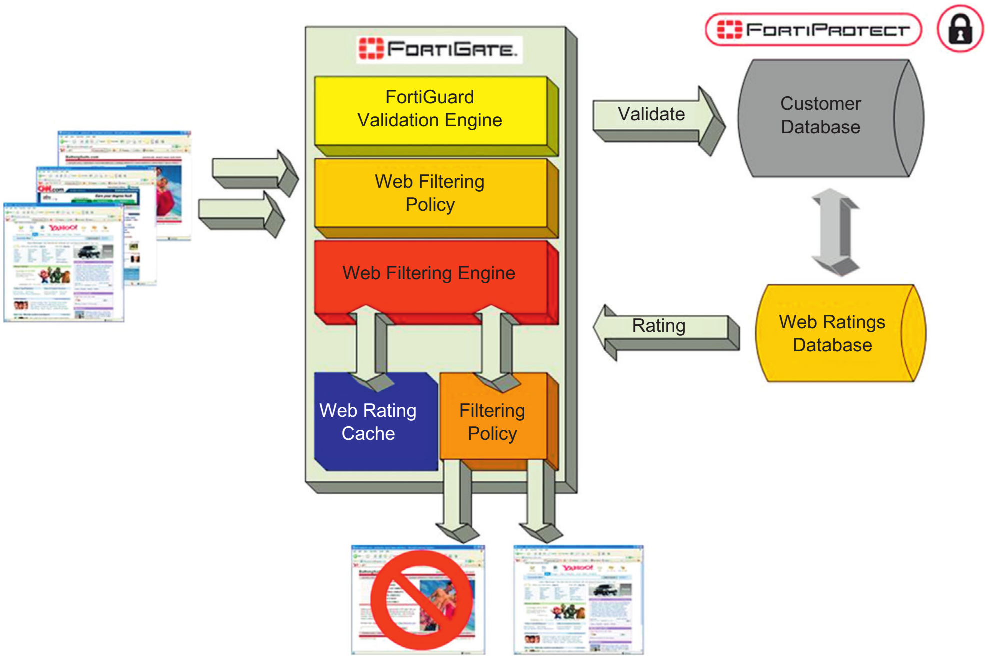

FIGURE e66.7 The flow of web site categorization and distribution of the updated lists to clients.

items, they can click a button that allows them to access the site.

Integration with Spam Filtering tools

Many content-filtering providers have a related component that inspects mail. That also includes the coordinates policy with the content-filtering gateway.

Spyware and Malware Categories

Most new content-filtering technology goes beyond just blocking offensive content. The same technology is looking for and blocking malware and spyware in HTTP data. Don't select an enterprise product without this feature.

Integration with Directory Servers

The easiest way to manages content filtering that requires granular user-lever control is to set up groups within directory servers. For example, Trusted User Groups, Executive User Groups, Owner User Group, and Restricted User Group will have different browsing policies. Some companies create role based access, choosing to create a category for HR and Finance, etc. and assign policies based on these roles.

Language Support

The content-filtering gateway must have support for multiple languages or the surfer will just find Spanish porn sites, for example. Typically a global ratings database will support multiple languages.

Financial Considerations are Important

Don't forget that a content filter project includes some of these items when calculating total cost of ownership for ROI payback:

- Licensing costs: Per user or per gateway.
- Hardware needed to run the solution; don't forget about a server for reporting
- Installation: Can you do it yourself or do you need a consultant or the manufacturer to help?
- Maintenance: Support and updates are necessary to keep your solution current.
- Ongoing administration from your IT staff.
- Patching, scanning, remediation by your IT staff.
- Some content filters need add-on server and license costs, for example:
  - ISA Server
  - MS Server
  - Logging Server
  - Analyzer Server
  - AV Server
  - Firewall
- Some content-filtering systems require integration costs with third-party enforcement points such as a firewall.

Reporting is a Critical Requirement

Reporting is a critical component of any content filtering solution, not only because it is key to compliance for industry specific regulations, but also because there is so much information to learn from logging and reporting. Real-time visibility to Internet usage, historical trending of Web traffic, and detailed forensic reporting help gauge user intent, help in enforcing Internet use policies, and enable retention of archived records to satisfy legal requirements and aid in regulatory compliance.

All web filtering companies will have a reporting module or product you can buy, and most will give you the basics like, who, what, when, where. In addition to the basics, many will have predefined report packages with useful information for management or the security team. Here are a couple of important predefined reports you may want to look for:

- *Management reports:* Management reports tend to give a high level overview of the environment. Most don't get in to detail on who did what, but focus on resource utilization, security overview, and any benefits of having the solution; for example if it caches, the amount of bandwidth that was saved during the reporting period.
- *Summary reports:* Summary reports are exactly what it sounds like, it gives a summary of traffic during the reporting period. Most will include a top talker and top sites, along with resource utilization and security overview.
- *User detail reports:* User level reports give you a complete picture of what someone has been doing over a period of time. Most will get very specific with the destination, category, object URL, time spent, amount downloaded, etc.
- HR reports: Human Resources reports typically contain the same information as the detail reports and also highlight denied requests, recreational categories, etc.
- Additionally this information is logged for reporting purposes:
- Source IP
- Destination IP
- URL
- Policy Action (allow, block, monitor)
- Content Category

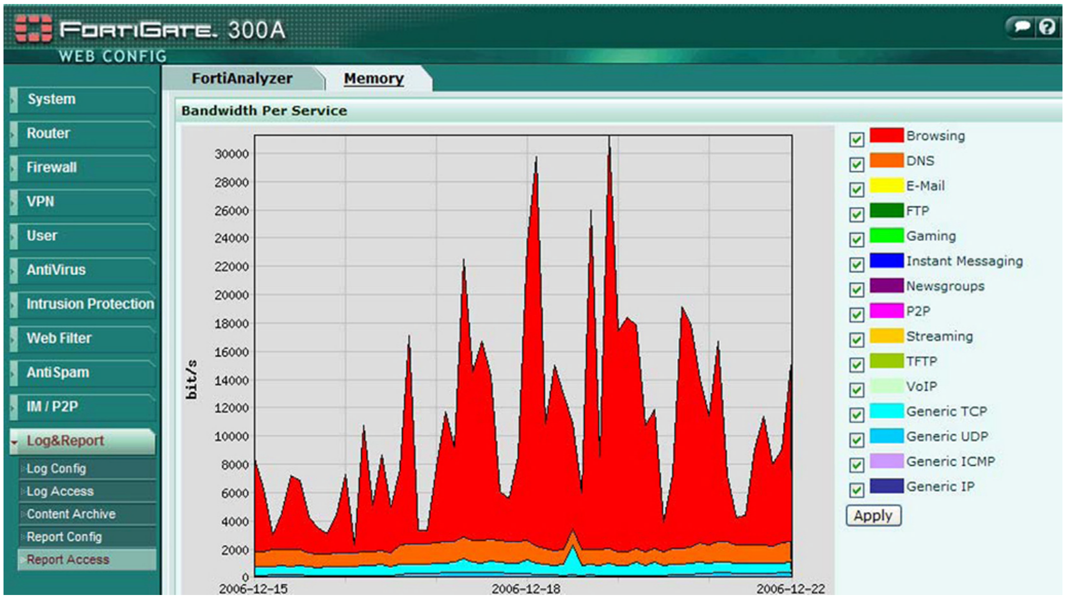

FIGURE e66.8 A bandwidth monitoring report from Fortinet.

Bandwidth Usage

Content-filtering systems should have the ability to display current protocol usage and report on patterns. Bandwidth savings give the most rapid ROI and need to be measurable. Figure e66.8 shows a bandwidth monitoring report from Fortinet.

Precision Percentage and Recall

The accuracy and efficacy of content-filtering systems are measured by precision and recall. Precision is the percentage of the number of relevant Web sites retrieved compared to the total number of irrelevant and relevant Web sites retrieved. Recall is the percentage of the number of relevant records retrieved compared to the total number of relevant records in the database. There is an inverse relationship between these two metrics that cannot be avoided: Maximizing one minimizes the other, and vice versa. Precision and recall must be considered together. A single metric of adding the precision and recall together is a good overall indication of the accuracy and efficacy.

The categorization of Web sites is an information retrieval process whereby each URL or Web page can be considered a record. A correctly categorized URL is a relevant record retrieved, whereas an incorrectly categorized URL is an irrelevant record retrieved. The objective of Web filtering is to block Web pages that are designated to be blocked and allow Web pages that are permitted. Web filtering precision is a measure of underblocking, or letting pages through that should be blocked. Higher precision leads to lower underblocking.

Web filtering recall is a measure of overblocking. Overblocking results from false positives and means blocking pages that should not be blocked. High recall leads to fewer false positives and lower overblocking. A perfect Web filtering system would have 100% precision and 100% recall, or a score of 200% overall.

A customer's Internet access policies dictate the Web sites to block, and typically all Web sites that are potentially liable, objectionable, or controversial are blocked.

Technical Support Challenges

Ensuring that your content filtering solution is not to blame for mysterious issues while surfing can be an ongoing IT support challenge. For example here is the trouble shooting flowchart from Bluecoat. See Figure e66.9.

9. RELATED PRODUCTS

Instant messaging, IRC, FTP, telnet, and especially email are all forms of communication that can be inspected with content-filtering technology. Also, more and more companies are integrating DLP (Data Leakage Prevention) technologies to reduce the risk of confidential, HIPPA, PCI, and PII information from leaking out over Internet connections. DLP inspection and blocking enforce data leakage and encryption policies.

Internet accountability software is a type of computer software that provides detailed reports that account for user behavior, surfing history, chat sessions, and actions on the Internet. Internet accountability software is used for various reasons, court-mandated sanctions, company

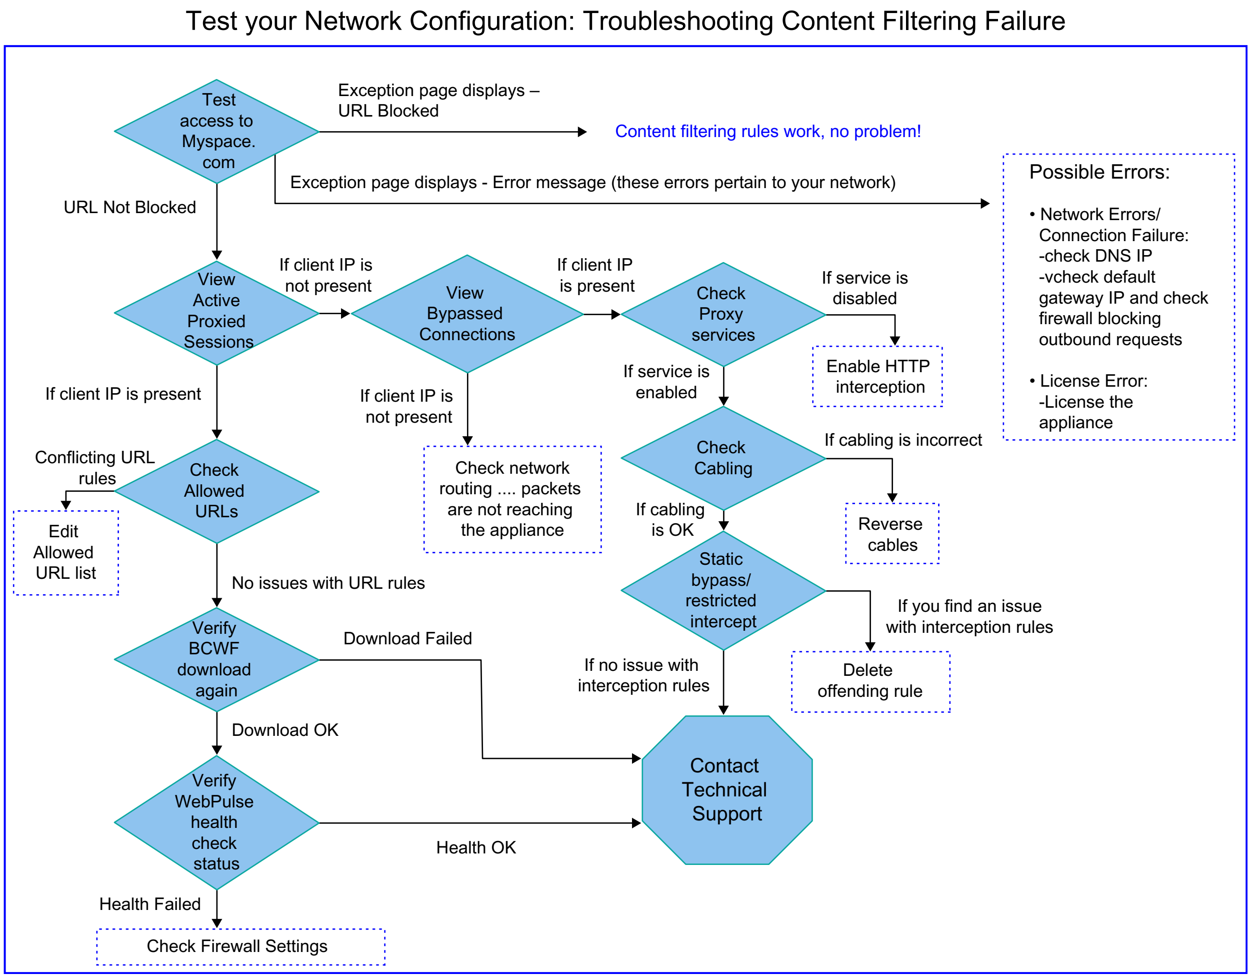

FIGURE e66.9 Trouble Shooting Content Filtering.

policy obligations, and as a recovery step in porn addiction. Versions of accountability software monitor Internet use on a personal computer, or Internet use by a specific user on a computer. These software applications then generate reports of Internet use, monitored by a third party, that account for and manage an individual's Internet browsing.

The first vendor to offer Internet accountability software was Covenant Eyes. Available in March 2000, Covenant Eyes accountability software was developed to provide Internet users with a means of reporting their online activity to one or more "accountability partners." The term "accountability partner" is a well-known concept in addiction-recovery circles and 12-step programs, such as Alcoholics Anonymous and Sexaholics Anonymous. Accountability partners have access to a user's Internet browsing record, which eliminates the anonymity of Internet use, thus providing incentive to not view Internet pornography or other explicit sexual images online. Today there are several accountability software providers: Covenant Eyes, Promise Keepers, K9 Web Protection, and X3watch.

10. SUMMARY

Content filtering is a tool and like any tool, knowing how to use it correctly will help you accomplish your goal. Whether you're a CEO looking to manage productivity or a parent protecting your children from the dangers of the Internet, content filtering is likely something you will have to think about at some point. We've considered the motivations for content filtering, examined the various methods, and highlighted a few market leading products, which should give you a good idea of what you will need to consider when choosing a solution. We have also touched on just a few common methods used to bypass content filtering and how a diligent administrator can use the tools at their disposal to discover this type of activity. Content filtering is a fast-paced battle of new technologies and the relentless trumping of these systems by

subversion and evasion. Altruistic development efforts by passionate programmers on a mission to support citizens in countries that block access to content will win, then lose, and then win again in a never-ending cycle. Other challenges include employees and kids who don't understand all the risks and don't think the abuse of a school-or company-provided computer and network is a big deal. Add new technologies, Web 2.0 applications, YouTube, and streaming sites, and the challenges and arguments for content filtering will not end anytime soon.

As we have explored, content filtering and its three objectives—accuracy, scalability, and maintainability—are at odds with each other. Accurate blocking makes it hard to scale and maintain, and easily scalable and maintainable systems are not as accurate. Companies that make content-filtering technology are attempting to make these challenges easier to manage and maintain.

Content filtering is sometimes controversial, and the law is frequently changing in the U.S. and internationally. IT policies try to cope and are being updated every year to deal with new legal issues.

Content filtering is morphing and aggregating with other technologies to address multifaceted threats. Today companies should be considering a defense in layers strategy, for example managing malware - using content filtering and anti-virus scanning at the gateway and anti-virus software at the desktop. If one control fails, there are backups in place to pick up the slack. In the high-stakes chess game of content filtering, the censors and policy enforcers are always perpetually destined to have the worst move in chess: the second to last one.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Casual business relatad Web surfing has caused many businesses countless hours of lost productivity and occasionally hostile work environments have been created by employees who view and download offensive content.
2. True or False? There are many reasons companies consider implementing content filtering, which can range from improving employee productivity, to blocking web based threats, and even prevent data leaks.
3. True or False? Financial organizations have unique privacy and security concerns due to the fact that they need to protect their customer's personally identifiable information such as credit card numbers, Social Security numbers, and other financial related information which means they have room for error.
4. True or False? ISPs have unique motivations with regards to content filtering.
5. True or False? In the United States, the threat from websites that host malicious software presents a significant risk which cannot be easily managed through content filtering.

Multiple Choice

1. The use of __________ or ____________ varies widely in public libraries in the United States, since Internet use policies are established by local library boards.
   - **A.** Reputation
   - **B.** Internet filters
   - **C.** Log
   - **D.** Encrypted
   - **E.** Content-control software
2. There are many ways parents can protect their children from age inappropriate material on the Internet; and, ________ should be one of them?
   - **A.** Opinity
   - **B.** Web content filtering
   - **C.** Scale
   - **D.** Access
   - **E.** Active monitoring
3. There are many technologies that can be used to categorize:
   - **A.** Organizations
   - **B.** Rapleaf
   - **C.** Worms
   - **D.** Content
   - **E.** Security
4. The _______ method allows the creation of a blacklist dictionary that contains keywords or phrases?
   - **A.** Keyword lists
   - **B.** Denial of service attack
   - **C.** Venyo
   - **D.** Port traffic
   - **E.** Taps
5. What contain full and/or partial URLs, which are compared to the URL in an HTTP get request?
   - **A.** Systems security plan
   - **B.** TrustPlus
   - **C.** Denying service
   - **D.** Decision making
   - **E.** URL lists

EXERCISE

Problem

Why does one need content filtering?

Hands-On Projects

Project

Will content filtering slow down an Internet connection?

Case Projects

Problem

Will users who choose not to filter be affected by content filtering implementation?

Optional Team Case Project

Problem

What happens when users are denied access to a site? Will they know that the content filter blocked the site?

Appendix eK

Answers To Review Questions/Exercises, Hands-On Projects, Case Projects And Optional Team Case Project By Chapter

John Vacca

CHAPTER 1: BUILDING A SECURE ORGANIZATION

Review Questions/Exercises

True/False

1. True
2. False
3. True
4. False
5. True

Multiple Choice

1. E
2. D
3. A
4. D
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The SAT should examine: Access control policy; procedures addressing access enforcement and dual authorization; security plan; information system design documentation; information system configuration settings and associated documentation; list of privileged commands requiring dual authorization; list of approved authorizations (user privileges); and, other relevant documents or records.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The SAT should examine: Access control policy; procedures addressing information flow enforcement; information system design documentation; information system configuration settings and associated documentation; information system baseline configuration; list of information flow authorizations; information system audit records; and, other relevant documents or records

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The SAT should examine: Security assessment and authorization policies and procedures; and, other relevant documents or records. They should also interview organizational personnel with security assessment and authorization responsibilities.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The SAT should examine: Contingency planning policy; procedures addressing contingency operations for the

information system; contingency plan; security plan; and, other relevant documents or records. They should also interview organizational personnel with contingency planning and plan implementation responsibilities.

CHAPTER 2: A CRYPTOGRAPHY PRIMER

Review Questions/Exercises

True/False

1. False
2. False
3. False
4. True
5. True

Multiple Choice

1. A, C
2. E
3. B
4. E
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The risk manager should do the following to fix the problem:

1. Listen for signs of complexity.
2. Know which areas of crypto are very hard, and which are simple.
3. If your team has to do something tricky (and you know that randomness is very tricky) then encourage them to do it clearly and openly.
4. If you are dealing in high-security areas, remember that only application security is good enough.
5. Do not distribute your own fixes to someone else's.
6. A good high-security design always considers what happens when each component fails in its promise.
7. Teach your team to work on the problem, not the people.
8. Do not believe in your own superiority.
9. If you've made a mistake, own it.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Random bit strings required for the generation of cryptographic keys should be obtained from an approved Random Bit Generator (RBG). The RBG should either provide full entropy output or have been instantiated at a security strength that meets or exceeds the security strength required to protect the data that will be protected by the key.

The output of the approved RBG should be used to either generate the key directly or used as a seed to generate the key according to approved criteria. An example of a key that can be directly generated is an AES or DSA private key; an example of a key that is generated from a seed is an RSA key, whereby the seed is used as a starting point to find a prime number that meets approved criteria. Thus, key generation is performed within a key-generating module (a cryptographic module in which keys are generated).

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Asymmetric algorithms, also known as public key algorithms, require the use of asymmetric key-pairs, consisting of a private key and a corresponding public key. The key to be used for each operation depends on the cryptographic process being performed (digital signature generation or key establishment). Each public/private key pair is associated with only one entity; this entity is known as the key pair owner. The public key may be known by anyone, whereas the private key must be known and used only by the key pair owner. Key pairs should be generated by:

- The key-pair owner
- A trusted party that provides the key pair to the owner in a secure manner. The trusted party must be trusted by all parties that use the public key.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Symmetric key algorithms use a single key to apply cryptographic protection to information (transform plaintext data into ciphertext data using an encryption operation) and to remove or verify the protection. Keys used with symmetric key algorithms must be known by only the entities authorized to apply, remove or verify the

protection, and are commonly known as secret keys. A secret key is often known by multiple entities that are said to share or own the secret key, although it is not uncommon for a key to be generated, owned and used by a single entity (for secure storage). A secret key should be generated by:

- One or more of the entities that will share the key.
- A trusted party that provides the key to the intended sharing entities in a secure manner. The trusted party must be trusted by all entities that will share the key.

CHAPTER 3: DETECTING SYSTEM INTRUSIONS

Review Questions/Exercises

True/False

1. True
2. True
3. True
4. False
5. False

Multiple Choice

1. B
2. A
3. C
4. A
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Under normal conditions, the TCP sequence number changes whenever a host sends a packet to a new system. In the exhibit, us.us.us.44 and us.us.us.50 are targeted using the same TCP sequence number of 2410044679.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The HEAD request is used obtain meta information about the requested resource without actually receiving the body of the file. Alternatively, the GET request actually retrieves the desired resource if it is found on the Web server. HEAD requests speed up the scan because the attacker's client application does not need to wait for the file to be retrieved when it is found on the targeted server.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Logging in via telnet; as well as, accessing a CGI program via HTTP, requires the TCP connection to be fully established, which is difficult to accomplish if the attacker uses a spoofed source address. ICMP-based ping packets, however, are stateless, and are often spoofed, especially when targeting a network broadcast address in a Smurf-like attack.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

If multiple systems on a LAN get assigned the same IP address, they will each try convincing their neighbors that their MAC address is the correct address for communicating with the IP address in conflict.

CHAPTER 4: PREVENTING SYSTEM INTRUSIONS

Review Questions/Exercises

True/False

1. False
2. True
3. False
4. False
5. False

Multiple Choice

1. A
2. E
3. A, B, D
4. D
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

You will need to examine the system and information integrity policy; procedures addressing information system monitoring tools and techniques; information system design documentation; information system monitoring tools and techniques documentation; information system configuration settings and associated documentation; information system protocols; and, other relevant documents or records. You will also need to examine the information system-wide intrusion detection and prevention capability.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The company implemented a wide range of intrusion prevention capabilities/services to provide 24/7 monitoring, instant alerts and in-depth threat analysis. The company's intrusion prevention capabilities/services should put it on track to achieving ISO 27001 accreditation. The company also benefited by gaining 24/7 responsiveness and in-depth threat analysis; the IT team saved the expense of adding additional members to its staff; compliance with diverse local legislation secured customer confidence and drove the business; and, it's multinational parent company approved the security infrastructure.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

To safeguard its network and the patients it serves, the medical center found a powerful IPS security solution that could continuously protect its high-throughput network without compromising network performance. The medical center's Intrusion Prevention System (IPS) provided the pervasive and proactive protection against malicious attacks by indicating where on the network a threat originated; thus, making it less difficult and time consuming for its IT staff to identify and cleanse infected departments before worms and viruses spread further. The IPS that was implemented was cost-effective and interoperated transparently with the medical center's multivendor infrastructure. More importantly, though, this IPS security solution did deliver pervasive protection in advance of threats; thus, leaving the medical center less vulnerable to evolving cyber attacks.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research. The following is a list of the basic IPS questions that a company might ask their vendors:

1. Can your IPS security vendor refer you to customers who are running in-band devices with a high percentage of blocking filters turned on?
2. Does your IPS security solution block bad traffic without blocking good traffic?
3. Does your IPS security solution protect not just your network perimeter, but also key points within the core of your network?
4. Does your IPS security solution provide attack coverage that is broad and deep?
5. Does your IPS security solution provide the performance needed to deeply inspect traffic without slowing down the network or business applications?
6. Does your IPS solution support maximum network and application availability?
7. How accurate is your IPS security solution attack coverage?
8. How timely and up to date is the attack coverage?
9. Is your IPS security solution in-band?

CHAPTER 5: GUARDING AGAINST NETWORK INTRUSIONS

Review Questions/Exercises

True/False

1. False
2. False
3. True
4. True
5. False

Multiple Choice

1. B
2. A
3. C
4. E
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The company focused on a high availability network security solution. For the size of their network, a firewall was the right solution for the job. They installed two of them, working in a secondary failover mode.

The installation itself was a breeze, because the security company was able to pre-build the configuration at their offices. They also used their standard, rule-of-thumb security set, based on their past work with the vendor sales engineers. In addition, the security company spent no more than 30 minutes customizing the security policies for the various proxy agents that were needed. In the end, they were able to create a very secure network environment pretty much out of the box.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The solution services company provided firewalls at each school district location, for a total of 245 security appliances. This gave the school district full proxy firewall capabilities at each school and facility, providing protection against intrusions, viruses, worms, and spyware, from both external and internal sources.

Two of the company's highest-end firewalls were placed at the school district's data center in the central office. These appliances are specifically designed for complex networks and data centers, and provided multigigabit performance and Ethernet interfaces with fiber interface support. They also provided stateful packet and application-based proxy inspection, branch office and mobile user VPN capabilities, and zero day attack prevention to deliver a much higher level of security than systems that rely solely on signature analysis for protection.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

As a first step, the town purchased a software solution, which logged all attacks and alerted network administrators to their source IP addresses. The town then sought an enterprise-class network security solution that would proactively shield servers, desktops, and data automatically and minimize the need for manual intervention by its IT staff. After surveying the marketplace, the town selected an Intrusion Prevention System (IPS) to protect its network.

Protected by IPS, the town can now fulfill the country's initiative with complete protection against cyber threats. By examining every incoming packet at Gigabit speed and near-zero latency, the IPS maintains the integrity of the town's network; thus, allowing town employees to sustain their productivity and constituent service to effectively satisfy taxpayers' needs.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

The following are the basic benefits of IDS and IPS systems:

- Normal and intrusive malicious activities detected
- Proactive protection of network security infrastructure
- Operational efficiencies to a reduced need to react to event logs for protection
- Increased coverage against packet attacks and zeroday attacks

CHAPTER 6: SECURING CLOUD COMPUTING SYSTEMS

Review Questions/Exercises

True/False

1. True
2. True
3. False
4. False
5. True

Multiple Choice

1. B
2. B
3. D
4. D
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

To determine this, you should review and compare available solutions, including firewalls, patch management procedures, security monitoring and response methods, and other relevant data security measures.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

You should consider that cloud services are an increasingly attractive target for hackers. Some clouds have experienced direct malicious attacks, potentially exposing any information stored there. In other instances, the clouds have been the targets of denial of service attacks.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

1. Create a VPC.
2. Create and attach an Amazon VPC Internet gateway.
3. Create an Amazon VPC subnet.
4. Set up routing in the VPC to enable traffic to flow between the subnet and the Internet.
5. Set up a security group.
6. Launch a Linux instance in the subnet.
7. Assign an Elastic IP address to the instance. A Elastic IP address is a static, public address that you can assign to any instance in your VPC.
8. After you complete the tasks, you will have a VPC with a running instance in it. You can connect to the instance from your network using SSH.
9. Add Amazon S3 resources for storage.
10. Deploy a basic e-commerce web application.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

You should evaluate your existing incident response capabilities and determine if changes are needed before deciding whether to move to the cloud. Organizational policies and procedures may need to be updated to accommodate anticipated changes introduced by the addition of a cloud—based system. Any such changes should be made well in advance of the implementation and updated regularly.

CHAPTER 7: FAULT TOLERANCE AND RESILIENCE IN CLOUD COMPUTING ENVIRONMENTS

Review Questions/Exercises

True/False

1. False
2. False
3. False
4. False
5. False

Multiple Choice

1. C
2. C
3. E
4. E
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

AppSpace leverages on the Amazon EC2 (Elastic Compute Cloud) service and inherits the security features of Amazon Web Services. Security within Amazon EC2 is provided on multiple levels: The operating system (OS) of the host system, the virtual instance operating system or guest OS, a stateful firewall and signed API calls. Each of these items builds on the capabilities of the others. The goal is to ensure that data contained within Amazon EC2 cannot be intercepted by non-authorized systems or users and that Amazon EC2 instances themselves are as secure as possible without sacrificing the flexibility in configuration that customers demand.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Cloud computing architecture typically involves multiple cloud components communicating with each other

over application programming interfaces, usually in the form of web services. This architecture works by having multiple programs each doing one thing well and working together over universal interfaces. Complexity is controlled and the resulting systems are more manageable than their monolithic counterparts. The two most significant components of cloud computing architecture are known as the front end and the back end. The front end is the part seen by the client (the computer user). This includes the client's network (or computer) and the applications used to access the cloud via a user interface such as a web browser. The back end of the cloud computing architecture is the 'cloud' itself, comprising various computers, servers and data storage devices.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Scalability within a Cloud architecture is via dynamic (on-demand) provisioning of resources on a fine-grained, self-service basis near real-time, without users having to engineer for peak loads. Performance is monitored, and consistent and loosely coupled architectures are constructed using web services as the system interface. This makes for an extremely organic structure and is capable of overcoming performance bottlenecks through distributed and parallel computing grids.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

By using a combination of Elastic Load Balancing, Auto Scaling Groups and CloudWatch, you can create a very fault tolerant environment with very little effort. Amazons Elastic Load Balancer is defiantly is a very fault tolerant product, load balanced instances can be spread across regions, which means you can have up to 5–6 instances each behind a separate set of hardware. If somehow Amazon experiences an outage in one of the regions, you still have your application online. The Elastic Load Balancer will also monitor a port on each of the instances to check the health of the application running on the instance. In addition to health checks on the application, Amazon also does a health check of the hardware and will replace your instance on failure.

CHAPTER 8: SECURING WEB APPLICATIONS, SERVICES AND SERVERS

True/False

1. True
2. True
3. True
4. True
5. True

Multiple Choice

1. C
2. B
3. D
4. B, E
5. A, D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

There are two different types of mechanisms for coordinating Web services: Web services orchestration and Web services choreography. Web services orchestration is performed within an organization's SOA and concerns the use of existing Web services to create another Web service. Web services choreography is performed among multiple organizations' SOAs and describes relationships between Web services so that Web services understand how to interact with one another to perform a process. When invoking a Web service orchestration, the encapsulating Web service uses an orchestration engine to define which Web services will be invoked. In contrast, when invoking a Web service choreography, the sequence of Web services is more dynamic, and the decisions are made by the relationships defined between individual Web services rather than by a unifying orchestration engine.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Web services security is based on several important concepts, including:

- **Identification and Authentication**: Verifying the identity of a user, process, or device, often as a prerequisite to allowing access to resources in an information system.

- **Authorization**. The permission to use a computer resource, granted, directly or indirectly, by an application or system owner.
- **Integrity**. The property that data has not been altered in an unauthorized manner while in storage, during processing, or in transit.
- **Non-repudiation**. Assurance that the sender of information is provided with proof of delivery and the recipient is provided with proof of the sender's identity, so neither can later deny having processed the information.
- **Confidentiality**. Preserving authorized restrictions on information access and disclosure, including means for protecting personal privacy and proprietary information
- **Privacy**. Restricting access to subscriber or relying party information in accordance with Federal law and organization policy

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

There are several options available for securing Web service messages:

- **HTTP over SSL/TLS (HTTPS)**. Because SOAP messages are transmitted using HTTP, it is trivial to modify a Web service to support HTTPS.
- **XML Encryption and XML Signature**. These XML security standards developed by W3C allow XML content to be signed and encrypted. Because all SOAP messages are written in XML, Web service developers can sign or encrypt any portion of the SOAP message using these standards, but there is no standard mechanism for informing recipients how these standards were applied to the message.
- **WS-Security**. WS-Security was developed to provide SOAP extensions that define mechanisms for using XML Encryption and XML Signature to secure SOAP messages.

Each secure messaging option has its own strengths and weaknesses.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

The top threats facing Web services today are:

- **Message alteration**. An attacker inserts, removes or modifies information within a message to deceive the receiver
- **Loss of confidentiality**. Information within a message is disclosed to an unauthorized individual
- **Falsified messages**. Fictitious messages that an attacker intends the receiver to believe are sent from a valid sender
- **Man in the middle**. A third party sits between the sender and provider and forwards messages such that the two participants are unaware, allowing the attacker to view and modify all messages
- **Principal spoofing**. An attacker constructs and sends a message with credentials such that it appears to be from a different, authorized principal
- **Forged claims**. An attacker constructs a message with false credentials that appear valid to the receiver
- **Replay of message**. An attacker resends a previously sent message
- **Replay of message parts**. An attacker includes portions of one or more previously sent messages in a new message
- **Denial of service**. An attacker causes the system to expend resources disproportionately such that valid requests cannot be met.

The importance of the preceding threats may vary depending on an organization's needs and purpose. In some instances, messages need not be kept confidential, so loss of confidentiality is not a concern. Similarly, organizations may offer a Web service to the public. For example, a Web service that provides information about the current weather forecast need not be concerned if a request is from a falsified sender. Regardless, it is important to understand these threats and what technologies are available.

CHAPTER 9: UNIX AND LINUX SECURITY

Review Questions/Exercises

True/False

1. False

2. C
3. C
4. B
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

At that point, the company's incident response plan was triggered into action. Since the FTP server was not of a critical business value, it was decided to complete the investigation before redeploying the server and to utilize other channels for software distribution temporarily. The primary purpose of the investigation was to learn about the attack in order to secure the server against recurrence. The secondary focus was to trace the actions of the attacker.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Security administrators need to pay greater attention to locking down operating systems. Even with a security enhanced Linux (SELinux), you have to turn on the SE features. And, you have to know where they are to activate them.

Another major area of vulnerability is server passwords, which are administered manually. Security administrators need an automated scanning tool that searches all servers for conformity to commercial and military guidelines; and, identifies vulnerabilities. The operating system is a traditionally overlooked piece of Linux security. With the proper tools, this can be done easily and result in a far more secure operation.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The following are some of rlogin's possible security problems:

- All information, including passwords, is transmitted unencrypted (making it vulnerable to interception).
- The common practice of mounting users' home directories via NFS exposes rlogin to attack by means of fake .rhosts files.
- The protocol partly relies on the remote party's rlogin client providing information honestly (including source port and source host name).
- The .rlogin (or .rhosts) file is easy to misuse (potentially allowing *anyone* to login without a password).

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Security-conscious administrators should use SSH or another encrypted protocol as their method of interactive remote access. If the version of SSH is current and it is fully patched, the service is generally assumed to be safe. However, regardless of whether it is up to date and patched SSH can still be compromised via brute-force password-guessing attacks. Use public key authentication mechanism for SSH to thwart such attacks. For the other interactive services, audit passwords to ensure they are of sufficient complexity to resist a brute-force attack.

Minimizing the number of running services on a host will also make it more secure. Many services have been used to further exploits and some combinations of services (such as web servers and FTP servers that share published directories) are particularly prone to exploits.

CHAPTER 10: ELIMINATING THE SECURITY WEAKNESS OF LINUX AND UNIX OPERATING SYSTEMS

Review Questions/Exercises

True/False

2. False
3. False
4. True
5. False

Multiple Choice

1. E
2. D
3. D
4. C
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

For you to determine whether you think Linux is a secure operating system, there are a few pieces of information you should be aware of before making your decision:

- Linux, as well as other popular freely available operating systems, have thousands of people scrutinizing

each line of code, not only for possible exploits, but also to further audit its level of security. Closed operating systems have only a small staff of people to determine its level of security.

- UNIX, and UNIX-like operating systems such as Linux, have an established background to work from, and despite Linux's relative youth, it is still older than many commercial operating systems.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Some people think it is better to disable the ability to load device drivers using modules, because an intruder could load a Trojan module or himself load a module that could affect system security. However, in order to load modules, you must be root. The module object files are also only writable by root. This means the intruder would need root access to insert a module. If the intruder gains root access, there are more serious things to worry about than whether he/she will load a module. Modules are for dynamically loading support for a particular device that may be infrequently used. On server machines, or firewalls for instance, this is very unlikely to happen. For this reason, it would make more sense to compile support directly into the kernel for machines acting as a server. Modules are also slower than support compiled directly in the kernel.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

This is done intentionally to prevent remote users from attempting to connect via telnet to your machine as root, which is a serious security vulnerability, because then the root password would be transmitted in cleartext, across the network. Don't forget: potential intruders have time on their side, and can run automated programs to find your password.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

To enable shadow passwords, run pwconv as root, and /etc/shadow should now exist, and be used by applications. If you are using RH 4.2 or above, the PAM modules will automatically adapt to the change from using normal /etc/passwd to shadow passwords without any other change. The shadow passwords are a mechanism for storing your password in a file other than the normal /etc/passwd file. This has several advantages. The first one is that the shadow file, /etc/shadow, is only readable by root, unlike /etc/passwd, which must remain readable by everyone. The other advantage is that as the administrator, you can enable or disable accounts without everyone knowing the status of other users' accounts. The /etc/passwd file is then used to store user and group names, used by programs like /bin/ls to map the user ID to the proper username in a directory listing. The /etc/shadow file then only contains the username and his/her password, and perhaps accounting information, like when the account expires, etc. To enable shadow passwords, run pwconv as root, and /etc/shadow should now exist, and be used by applications. Since you are using RH 4.2 or above, the PAM modules will automatically adapt to the change from using normal /etc/passwd to shadow passwords without any other change. Finally, since you're interested in securing your passwords, perhaps you would also be interested in generating good passwords to begin with. For this, you can use the pam_cracklib module, which is part of PAM. It runs your password against the Crack libraries to help you decide if it is too-easily guessable by password-cracking programs.

CHAPTER 11: INTERNET SECURITY

Review Questions/Exercises

True/False

1. True
2. True
3. True
4. False
5. False

Multiple Choice

1. C
2. B
3. D
4. A
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

An organization should decide their authentication strategy by basing it on their user credential store location and the location of their clients on the Internet or an intranet.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Know your authorization options and choose the most appropriate one for your scenario. First decide if you want to use resource-based or role-based authorization. Resource-based authorization uses access control lists (ACLs) on the resource to authorize the original caller. Role-based authorization allows you to authorize access to service operations or resources based on the group a user is in.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Message security encrypts each individual message to protect sensitive data. Transport security secures the end-to-end network connection to protect the network traffic. So, with the preceding in mind, use the following criteria to decide whether to use transport security:

- Point-to-point.
- Streaming.
- Binding limitations.
- Authentication limitations.
- Performance.

Now, use the following criteria to decide whether to use message security:

- Intermediaries.
- Encryption flexibility.
- Binding limitations.
- Secure conversations.
- Authentication limitations.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

If your users are in Active Directory, consider using Windows, username, or Basic authentication. All of the following authentication schemes can be mapped to users in Active Directory:

- Windows authentication.
- Basic authentication.
- Username authentication.

CHAPTER 12: THE BOTNET PROBLEM

Review Questions/Exercises

True/False

1. False
2. True
3. False
4. True
5. False

Multiple Choice

1. D
2. C
3. E
4. C
5. E

Exercise

Solution

The following is a partial exercise solution. The botnet incident response team should be able to expand on the following questions and provide solutions:

1. How would the botnet incident response team identify all infected hosts?
2. How would the organization attempt to prevent the worm from entering the organization before antivirus signatures were released?
3. How would the organization attempt to prevent the worm from being spread by infected hosts before antivirus signatures were released?
4. Would the organization attempt to patch all vulnerable machines? If so, how would this be done?

5. How would the handling of this botnet incident change if infected hosts that had received the DDoS agent had been configured to attack another organization's Web site the next morning?
6. How would the botnet incident response team keep the organization's users informed about the status of the incident? What if e-mail services were overloaded or unavailable due to the worm?
7. What additional measures, if any, would the botnet incident response team use to take care of hosts that were not currently connected to the network (staff members on vacation, offsite employees who dial in occasionally)?

Hands-on Project

Solution

The following is a partial exercise solution. The botnet incident response team should be able to expand on the following questions and provide solutions:

1. How would the botnet incident response team determine which hosts within the organization were producing the traffic? Which other teams might assist the botnet incident response team?
2. After identifying a server that was producing the traffic, how would the botnet incident response team determine whether the server was infected with botnets?

Case Projects

Solution

The following is a partial exercise solution. The botnet incident response team should be able to expand on the following questions and provide solutions:

1. How would the botnet incident response team determine what vulnerability or configuration settings permitted the malicious mobile code to infect the systems?
2. How would the botnet incident response team determine what Web site or sites sent the malicious mobile code to the users' systems?

Optional Team Case Project

Solution

The following is a partial exercise solution. The botnet incident response team should be able to expand on the following questions and provide solutions:

1. Since the botnet is most likely a blended attack, how would the response differ from that for a worm?
2. Which attack vector would the organization focus its containment measures on first, and why?

CHAPTER 13: INTRANET SECURITY

Review Questions/Exercises

True/False

1. True
2. True
3. True
4. True
5. False

Multiple Choice

1. A
2. B
3. C
4. D
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

There are times when an intranet will encounter suspicious traffic, such as spam, phishing, spyware, adware and malware; so, deploying an effective email filter (and firewall) can help block the suspicious traffic from entering the network.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

There have been several cases reported of an intranet being attacked. A network-based intrusion prevention system (IPS) or an intrusion detection prevention system (IDPS) can offer great protection. They also can be deployed for monitoring network traffic and detecting and preventing well-known threats and attacks.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Unauthorized access happens much too often when an internal or external user (not authorized) gains access to

data and corporate information stored on an intranet. It may be wise to use some type of authentication like passwords, smart cards, or biometrics; in addition, to deploying a bastion host before a user has access to the intranet.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Too often are users gaining unauthorized access to systems from the Intranet. Businesses may want to use some type of intranet monitoring software to see what their employees are doing on the intranet or on their own PCs.

Network administrators want to know what happens on their network. This is both from a machine and sftware perspective; as well as, from a user perspective. This is monitoring the network. The idea is to watch what happens so that the network can keep functioning during business or critical times.

Intranet software sits on a server. It monitors all data traffic between the Internet and the intranet. Moreover, it can monitor all traffic on the intranet itself. It works by examining every Internet Protocol (IP) packet moving in and moving out of the intranet. It examines both the IP header and the data itself. The IP header keeps track of the address, source, and destination. The data can be documents, spreadsheets, e-mail, and so on.

So, with the preceding in mind, what should monitoring software provide the network administrator? It should provide information about who is logged on, who is sending e-mail, and who is signing in late or signing out early. It should record key strokes if necessary.

CHAPTER 14: LOCAL AREA NETWORK SECURITY

Review Questions/Exercises

True/False

1. False
2. False
3. False
4. False
5. True

Multiple Choice

1. B
2. C
3. D
4. E
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

You need to meet the following minimum requirements to connect to a local area network (LAN):

- A wireless capable computer or wireless card (802.11 a/g/n with WPA2-Enterprise encryption compatibility).
- A supported operating system is also needed: The operating system is the software that "runs" your computer and allows other software to be installed and used.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

In a traditional network, the company will need to consider Routers, Firewalls and SPAM filtering requirements for each site. The number of Routers, Firewalls and SPAM filtering devices will depend on how each site is connected to each other (dedicated lines, VPN or other). In addition, there will probably be a need for a requirement for a DMZ on some of the sites.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

A mapping entry in the application config file is one possible solution. It could help the organization do what it needed to do without any kind of reconfiguring of the network connections.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The company needs to gather more information, such as:

1. What model of Cisco Router they are using?

2. What type of WAN connectivity do they have?
3. How is their router connected to their LAN and WAN devices?

A basic topology with the specific devices and how they are interconnected, would be the most helpful way for the company to solve this problem.

CHAPTER 15: WIRELESS NETWORK SECURITY

Review Questions/Exercises

True/False

1. True
2. True
3. True
4. True
5. False

Multiple Choice

1. C
2. D
3. E
4. A
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Short for Wired Equivalent Privacy, WEP is a security protocol for wireless local area networks (WLAN), as defined in the 802.11b standard. WEP is designed to provide the same level of security as that of a wired LAN. LANs are inherently more secure than WLANs, because LANs are somewhat protected by the physical nature of their structure, having some or all part of the network inside a building that can be protected from unauthorized access. WLANs, which use radio waves, do not have the same physical structure and therefore are more vulnerable to tampering. WEP provides some security by encrypting data being transmitted over radio waves so that it is protected as it is transmitted from one end point to another. However, it has been found that WEP is not as secure as once believed. WEP alone is not sufficient security.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

A WEP key is basically an encryption password that is shared by an access point and a wireless client, allowing basic encryption and decryption of information between the access point and the client device. A WEP key will need to be added to your wireless client on your PC to access wireless resources. The WEP key for an organization can be obtained from an IT person responsible for your area or by contacting a Help Desk.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Using the risk assessment as its basis, the computer security department should concentrate on four areas for risk mitigation: physical security, access point (AP) location, AP configuration, and security policy. Analysis of physical security reveals that nonemployees are able to gain access to the building after checking in at the main desk. To ensure that only authorized employees and guests may access the building, the security department should recommend that Organization A adopt the use of photo identification, card badges, or biometric devices. The security team should physically secure the APs by installing them within the secured building facility, which requires users to have proper identification to enter.

The computer security department should minimize the possibility that unauthorized users will access the WLAN from outside the building. The security department should also evaluate each AP to determine the network vulnerabilities, such as eavesdropping. Network engineers should conduct a site survey to determine the best physical location for the APs, to reduce the threat of eavesdropping. This involves physically mapping where users have wireless access to the network. The security department realizes that with a high-gain antenna, attackers will still be able to eavesdrop on wireless network traffic. To offset this risk, the department proposes placing the WLAN outside the firewall and passing traffic through a VPN that supports high-level encryption. This configuration will greatly reduce the risks associated with eavesdropping.

Next, the computer security department should focus on vulnerabilities related to AP configuration. Because many APs retain the original default factory password setting, the computer security department should choose a robust password to ensure a higher level of assurance. In conjunction with management and network administrators, the security department should develop a security policy that requires passwords to be regularly updated and have a minimum length of eight alphanumeric

characters. The policy should include the provision to change the encryption setting from "no encryption" to 128-bit encryption. The policy should further deal with the Medium Access Control (MAC) and Access Control List (ACL) usage.

To provide an additional level of access security, the department should allow the use of MAC ACLs whenever possible. The policy should also addresses the use of SNMP. The computer security department decides to disable remote SNMP, because of the related threat and only allows it from internal hosts. Finally, since many vendors use default shared authentication keys, unauthorized devices can gain access to the network if they know the default key. Consequently, the security department should stipulate the use of a username and password as supplemental authentication to APs.

The security department should add additional policies to address software upgrades and use of the network. The policy should require system administrators to test and update security patches and upgrades; as soon as, the vendor makes them available. Frequent patches and upgrades will help reduce the possibility of attack on the older, faulty version of the software. Check for a comprehensive list of known vulnerabilities in major software packages and hardware products. The policy should also strongly discourage users from processing proprietary or employee personal data when connected from their laptops to the WLAN, thus helping to reduce the risk of personnel data exploitation. Additionally, the policy should state that if a laptop is lost or stolen, the employee to whom the laptop belongs to will promptly notify the security department. This will ensure that the security department can quickly identify the IP address assigned to the laptop and prevent that IP address from accessing the network.

As an additional security measure, the security department should recommend that Organization A incorporate the use of an IDS. The IDS will help determine whether unauthorized users are attempting to access, have already accessed, or have compromised the network. The department should view an IDS as a useful tool in protecting Organization A's network and, more importantly, the data that traverses it.

Finally, the security department should present the manager with a risk assessment, which includes the countermeasures described in the preceding. The risk assessment also should include an update of the residual risk with the proposed measures in place. Realizing that the benefits of system operation now outweigh the residual risks, the manager should agree to implement the WLAN. However, the security department should warn that although the risk assessment is thorough, WLAN technology is continually changing along with the security vulnerabilities that malicious users expose.

The security department should also offer encryption algorithms as an example. As encryption-breaking programs become more sophisticated, malicious users may expose more software flaws in vendor programs or weaknesses in encryption algorithms. It should be pointed out that users always represent the weakest link in a security chain. The organization must continue to educate the user community about the risks that wireless technologies pose, reiterating, for example, how important it is not to give others their usernames and passwords and not to execute programs that come from unknown sources. In conclusion, the security department should convey that the strategy is one of defense-in-depth. For example, the WEP encryption should be enabled with random keys; use of MAC ACLs, and a IPsec-based VPN overlay should be deployed. The security department should also monitor the appropriate standards organizations and the availability of products, such that the optimal security solution (most secure and cost-effective) for the enterprise can be determined.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

A canvas of user attitudes reveals that most of the organization's users do not appreciate the implications of losing a mobile device and the loss of sensitive organizational data. The network administrators should test the devices and set up a one-hour training course for the employees that will be using the mobile devices. During the training course, the users are given the security policy and documentation explaining the security risks associated with the devices. The security team also recommends instituting security policies that address the appropriate uses of mobile devices, the use of random inventory and security audits, and the users' responsibilities and liabilities. The security policy should specify the type of information users can store on the mobile device, proper handling of mobile devices, password requirements (frequency of change, minimum character length), procedures for reporting a lost or stolen mobile device, and any disciplinary actions that may result from misuse.

The security department completes its risk assessment and cautions that even though it has done a thorough analysis of the mobile devices, there are still risks given the fast pace with which mobile devices are evolving and the likelihood that malicious users will try to exploit any new or existing vulnerability. Organization C determines that the operational benefits outweigh the residual risks of the mobile devices and moves forward with the purchase.

Organization C considers the protection of sales-leads information paramount. Encryption software is used to encrypt database files stored on the PC and the mobile device. Users are encouraged to synchronize their handheld devices every other day; consequently, Organization C does not purchase backup storage modules. The security department realizes that infrared (IR) beaming has important benefits and decides not to prohibit IR beaming completely. However, it does recommend that users keep IR ports closed during periods of nonuse. The sales force also needs to update the corporate sales tracking database, view inventory information, and access corporate e-mail. It is decided that access to corporate resources will be through a VPN.

Before issuing the mobile devices to its sales force, the department ensures that the default settings of the Bluetooth cards are changed to comply with the organization's security policy. The security team upgrades its existing antivirus software to allow it to screen data being transferred to the PC during synchronization. The security team also installs software that automatically prompts the users to enter a password to access the device after 15 minutes of inactivity on all the mobile devices. The security team labels the devices and issues the devices to users with the proper security settings. The security team performs regular audits and follows vendor sites and security mailing lists for security news about handheld devices and applications.

CHAPTER 16: WIRELESS SENSOR NETWORK SECURITY

Review Questions/Exercises

True/False

1. False
2. True
3. False
4. False
5. False

Multiple Choice

1. C
2. C
3. B
4. E
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Wireless sensor network data acquisition is an extension of PC-based data acquisition to measurement applications where cables are inconvenient or impractical. NI CompactDAQ combines IEEE 802.11 wireless technology and support for over 50 measurement modules with the flexibility of NI LabVIEW software for remote monitoring and control of electrical, physical, mechanical, and acoustic signals. The NI cDAQ-9191 chassis houses a single C Series module and delivers IEEE 802.11b/g *and* Ethernet connectivity back to a host PC, while the NI cDAQ-9181 provides Ethernet connectivity only. C Series modules offer direct network sensor connections and built-in signal conditioning for a variety of measurements, including temperature, strain, high-voltage digital I/O, acceleration, current, and voltage. You can use C Series modules interchangeably for a variety of measurement and control applications across several platforms, including both NI CompactDAQ and CompactRIO.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Unlike most wireless sensors or wireless sensor networks, wireless data acquisition devices are meant to stream data continuously back to a host PC or laptop. A wireless sensor node is typically a low-power, autonomous battery-operated device intended for long-term deployment in applications where measurements are needed only every few minutes, hours, or even days. Wi-Fi data acquisition devices, on the other hand, behave in much the same way as a USB data acquisition device a host PC collects data continuously (in real time) as the device acquires it. The data acquisition device may be battery-operated, but the focus is on the measurement versus the battery life. Also, Wi-Fi Wi-Fi NI CompactDAQ chassis use the near-ubiquitous wireless networking standard, IEEE 802.11, instead of ZigBee or other IEEE 802.15.4 variants because of its higher bandwidth and broader applicability. Finally, because the NI CompactDAQ chassis uses the same NI-DAQmx driver software as other NI data acquisition devices, you can develop your applications using NI LabVIEW; LabWindows/CVI; ANSI C/C++; or Microsoft C#, Visual Basic, or Visual Basic .NET.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Sensors enable a security system to monitor entryways such as doors and windows. A wireless security sensor can be added to an existing security system that uses wiring to connect sensors to the control panel. This eliminates safety concerns that otherwise would occur if wires had to be strung for great distances, such as from a backyard shed's door. A wireless security sensor kit can be acquired from select hardware and home and garden shops. Adding wireless security sensors requires the use of a few common household tools and does not negatively affect the wired security system in any way.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

A window sensor is designed to register a disturbance when its companion sensor plate is no longer making contact. You can install window sensors to use with a wireless burglar alarm without the need for any extra wires or special tools. A tool common to most homes is all that is needed, along with the wood screws that come with the window sensor when it is purchased from a hardware store or security store supplier.

CHAPTER 17: CELLULAR NETWORK SECURITY

Review Questions/Exercises

True/False

1. True
2. True
3. False
4. True
5. True

Multiple Choice

1. D
2. D
3. C
4. A
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Compared to Wired Networks, Wireless Cellular Network security has a lot of limitations.

1. Open Wireless Access Medium: Since the communication is on the wireless channel, there is no physical barrier that can separate an attacker from the network.
2. Limited Bandwidth: Although wireless bandwidth is increasing continuously, because of channel contention everyone has to share the medium.
3. System Complexity: Wireless systems are more complex due to the need to support mobility and making use of the channel effectively. By adding more complexity to systems, potentially new security vulnerabilities can be introduced.
4. Limited Power: Wireless Systems consume a lot of power and therefore have a limited time battery life.
5. Limited Processing Power: The processors installed on the wireless devices are increasing in power, but still they are not powerful enough to carry out intensive processing.
6. Relatively Unreliable Network Connection: The wireless medium is an unreliable medium with a high rate of errors compared to a wired network.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

There are several security issues that have to be taken into consideration when deploying a cellular infrastructure. The importance of which has increased with the advent of advanced networks like 3G and 4G.

1. Authentication: Cellular networks have a large number of subscribers, and each has to be authenticated to ensure the right people are using the network. Since the purpose of 3G and 4G is to enable people to communicate from anywhere in the world, the issue of cross region and cross provider authentication becomes an issue.
2. Integrity: With services such as SMS, chat and file transfer it is important that the data arrives without any modifications.
3. Confidentiality: With the increased use of cellular phones in sensitive communication, there is a need for a secure channel in order to transmit information.
4. Access Control: The Cellular device may have files that need to have restricted access to them. The device might access a database where some sort of role based access control is necessary.
5. Operating Systems In Mobile Devices: Cellular Phones have evolved from low processing power, adhoc supervisors to high power processors and full fledged operating systems. Some phones may use a Java Based system, others use Microsoft Windows CE and have the same capabilities as a desktop

computer. Issues may arise in the OS which might open security holes that can be exploited.

6. Web Services: A Web Service is a component that provides functionality accessible through the web using the standard HTTP Protocol. This opens the cellular device to variety of security issues such as viruses, buffer overflows, denial of service attacks etc.
7. Location Detection: The actual location of a cellular device needs to be kept hidden for reasons of privacy of the user. With the move to IP based networks, the issue arises that a user may be associated with an access point and therefore their location might be compromised.
8. Viruses And Malware: With increased functionality provided in cellular systems, problems prevalent in larger systems such as viruses and malware arise. The first virus that appeared on cellular devices was Liberty. An affected device can also be used to attack the cellular network infrastructure by becoming part of a large scale denial of service attack.
9. Downloaded Contents: Spyware or Adware might be downloaded causing security issues. Another problem is that of digital rights management. Users might download unauthorized copies of music, videos, wallpapers and games.
10. Device Security: If a device is lost or stolen, it needs to be protected from unauthorized use so that potential sensitive information such as emails, documents, phone numbers etc. cannot be accessed.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Due to the massive architecture of a cellular network, there are a variety of attacks that the infrastructure is open to.

1. Denial Of Service (DOS): This is probably the most potent attack that can bring down the entire network infrastructure. This is caused by sending excessive data to the network, more than the network can handle, resulting in users being unable to access network resources.
2. Distributed Denial Of Service (DDOS): It might be difficult to launch a large scale DOS attack from a single host. A number of hosts can be used to launch an attack.
3. Channel Jamming: Channel jamming is a technique used by attackers to jam the wireless channel; and, therefore deny access to any legitimate users in the network.
4. Unauthorized Access: If a proper method of authentication is not deployed then an attacker can gain free access to a network and then can use it for services that he might not be authorized for.
5. Eavesdropping: If the traffic on the wireless link is not encrypted then an attacker can eavesdrop and intercept sensitive communication such as confidential calls, sensitive documents etc.
6. Message Forgery: If the communication channel is not secure, then an attacker can intercept messages in both directions and change the content without the users ever knowing.
7. Message Replay: Even if communication channel is secure, an attacker can intercept an encrypted message and then replay it back at a later time and the user might not know that the packet received is not the right one.
8. Man In The Middle Attack: An attacker can sit in between a cell phone and an access station and intercept messages in between them and change them.
9. Session Hijacking: A malicious user can highjack an already established session, and can act as a legitimate base station.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

While there are several security mechanisms available in wireless cellular networks, continued research is going on to provide new and even more secure mechanisms for cellular security. For example:

1. New Authentication Scheme with Anonymity For Wireless Networks:

   When a mobile user is roaming, it is necessary to provide anonymity to the users so that malicious parties are unable to associate the user with a particular session. The most basic method to provide anonymity is to have a temporary identity (TID) instead of the real id of the user. There are several issues to consider when designing a security protocol for cellular networks. One, they have low computational power which means that algorithms that require high processing power are not suitable. Second, the error rate of messages increase on wireless networks as compared to cellular networks. Therefore, any mechanism that is designed should minimize message sizes and the number of messages in order to reduce the error rate.

2. Manual Authentication For Wireless Devices:
   This is a technique used by devices to authenticate one another by manually transferring data between the devices. This means that the users will enter some information using some form of input (keypad). Underneath they employ MAC algorithms for authentication. Although the scheme that is proposed is secure, it usability depends upon how many numbers (or alphabets) the users have to input.
3. Elliptic Curve Cryptography For Wireless Security:
   Elliptic Curve Cryptography (ECC) is a mechanism which uses points on an elliptic curve to encrypt/decrypt data. It has an advantage over the popular RSA algorithm in that it is much faster. 163 - bit ECC provides the same security as a 1024 bit RSA algorithm, and can be anywhere from 5 to 15 times faster depending on the platform. For example, in order to secure a 128 bit AES shared key and 521 - bit ECC provides the same level of security as an 15,360 bit RSA while being about 400 times faster.
4. Channel Surfing And Spatial Retreats:
   Defense against Wireless Denial Of Service DOS attacks are one of the most dangerous attacks because they can bring down an entire network. An adversary can either trying to fill the buffer in a network device, or can by pass the MAC layer and try to jam the channel. Channel Surfing is a technique where the transmission frequency is changed to one where there is no interference. Spatial Retreats is a technique where the wireless users move to a location where there is no interference.

CHAPTER 18: RFID SECURITY

Review Questions/Exercises

True/False

1. True
2. False
3. True
4. True
5. True

Multiple Choice

1. A
2. E
3. C
4. B
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Comprehensive automatic test methods ensure that no code exists in duplicate in any of the transponder types, and that the codes are programmed correctly in a readable manner. In each transponder, 39 bits of memory are reserved for the code. That translates into 239 (or about 550 billion) possible unique codes. If one were to assign all 550 billion codes to transponder with the smallest dimensions known today, specifically the ID-100 Microtransponders with their length of 12 mm, and then line these transponders up end to end, the resulting string would measure 6.5 million kilometers in length, which is about 160 times the circumference of the earth.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Unattended data capture is one of the stronger business benefits to RFID. And this leads to the question: How do you know that the data is secure and accurate? Work continues to develop new security protocols between the tag and reader, but the fact that the range of the technology is limited really does significantly minimize the risk. More important is the need for a robust wired and wireless network security methodology to ensure that as the RFID data moves around a corporation, and possibly over large geographic areas, it remains secure.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The first step in the case project is to conduct a risk assessment to help shape the final scope of the project and identify the most appropriate uses of the RFID technology, as well as potential controls to mitigate the accompanying risk. Some risks identified during the assessment are as follows:

- RFID systems could open a “backdoor” to the FSRC computer network, which could result in the compromise of mission-critical systems and research archives.
- Anyone eavesdropping on RFID transactions could compromise the privacy of patient medical records.

- The FSRC could be held liable for violations of the privacy provisions of Health Insurance Portability and Accountability Act (HIPAA).
- The radio frequencies used by the RFID system could interfere with wireless patient sensors and medical telemetry devices, which could impact quality of care and research results.
- Dermal contact with RFID tags might be a potential vector for the transmission of some highly contagious diseases.

The risk assessment also concluded that some RFID risks were minimal or nonexistent in the FSRC environment. The worst case for expected patient and staff exposure to RF radiation was forecasted to be significantly below any level that might adversely affect their health. FSC already had a well-enforced policy that prohibits the storage of fuel or ordnance at the facility, and the use of potentially explosive material such as ether and oxygen tanks was tightly controlled. The likelihood that an adversary would attempt to use the FSRC RFID system to gather intelligence or target personnel was deemed negligible.

As a result of the risk assessment, the FSRC enhanced its network security policy to require that the RFID system be separated from other network systems using a firewall that permits only required data and management traffic to traverse the network boundary. The network security policy also was amended to require user authentication to all non-stationary RFID readers and encryption of wireless traffic between mobile readers and access points. Existing policy regarding secure server configurations and least privilege data access would extend to the RFID systems without requiring any modifications. The FSRC also decided that it would not institute a new requirement for wireless intrusion detection, but it would revisit this decision during the following fiscal year.

The FSRC also conducted a privacy assessment based on information collected during the risk assessment. As a result, the FSRC privacy policy was revised to account for the introduction of RFID technology. The revision noted that any patient data collected by the RFID system would be subject to the FSRC's internal procedures implementing HIPAA regulations. A final determination was made to update patient release forms to include a statement that inherent risks exist with wireless communications and that network security controls were implemented to help mitigate these risks. Based on the project charter and the updated security and privacy policies, the CIO led an interdisciplinary team of medical practitioners and information technology professionals to develop the business and functional requirements for the RFID system.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The project team began with a risk assessment, which identified a number of concerns, the most significant of which were as follows:

- An adversary could identify and target a vehicle containing RAD-regulated material.
- An adversary could eavesdrop on tag transactions to learn the characteristics of the material, which could help determine whether it is worth stealing.
- An adversary could damage or disable a tag, making it easier to steal material without detection.
- An adversary could alter sensor or manifest data stored on the tag in an effort to undermine the business processes for which the material is being used.
- The radiation from readers could accidentally cause combustion of collocated volatile materials when several of them are operating concurrently in close proximity.

To help address the risks, RAD established a policy that required that tagged items only be identifiable during embarkation, debarkation, and storage, but not during transport. The policy further stated that tag-reader communication should be authenticated whenever technically feasible with commercial-off-the-shelf systems. RAD also conducted a privacy assessment that identified that the system would handle Personally Identifiable Information (PII) due to the need to associate materials with particular individuals, although most such information was already contained in existing logs. Furthermore, RAD updated its privacy disclosure statement for employees and contractors to account for the new technology. Finally, it required that all personnel involved in handling of the tagged materials be provided RFID security and privacy awareness training. In addition, RAD already had a Hazards of Electromagnetic Radiation to Fuel (HERF) policy, but everyone agreed the introduction of the RFID system would require the agency to revisit the efficacy of these HERF-related controls.

CHAPTER 19: OPTICAL NETWORK SECURITY

Review Questions/Exercises

True/False

1. False
2. True

3. False
4. False
5. True

Multiple Choice

1. B
2. A
3. D
4. C
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Yes. Optical network security is one of the most robust features of a NAS optical storage server. A NAS optical storage server has a unified optical network security model enabled throughout all of the client protocols. Concepts such as Local Users, Local Groups, Share Level Passwords, User Level security, NT Domain Users, and NDS Users are usually supported.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Seamlessly. The optical network security model of a NAS optical storage server functions independently of any protocol that is accessing it. If a NetWare user logs in as Supervisor, for example, and sets privileges to a given directory to only NDS users named "Nate", then all other clients are denied access to this directory. If the administrator then adds a local user "Steve" to this same directory then a user from a Macintosh, Unix system, Microsoft or Novell Bindery client can access the directory as "Steve;" as well as, the NDS user "Nate." In this example all other users (regardless of protocol) are locked out of this directory.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Yes. Unlike other NAS servers, which only allow optical network security to be configured at the volume level, a NAS optical storage server allows security to be configured down to the directory level.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Yes. All of the methods of setting optical network security on physical volumes or directories are available for virtual volumes.

CHAPTER 20: OPTICAL WIRELESS SECURITY

Review Questions/Exercises

True/False

1. True
2. False
3. False
4. False
5. True

Multiple Choice

1. B
2. C
3. A
4. D
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The truth is that wireless fiber cabling is just as vulnerable to hackers as wired networks using easily obtained commercial hardware and software.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Setting up a fiber tap is no more difficult than setting up equipment for any other type of hack, wired or wireless. Optical wireless network exploits are accomplished by extracting light from the ultra-thin glass fibers. The first, and often easiest, step is to gain access to the targeted fiber optic cable. Hundreds of millions of miles of fiber cable stretch across the globe; there are more than 190 million miles in the United States alone. Although most of this cabling is difficult to access: It's

underground, undersea, encased in concrete, and run through walls and elevator shafts; plenty of cables are readily accessible for those willing to look. Some cities, for example, have detailed maps of their wireless fiber-optic infrastructure posted online in an effort to lure local organizations to hook into the network.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Bending light is the easiest method. It is also the most undetectable, since there is no interruption to the light signal. Commercially available clip-on couplers cost less than a thousand dollars; these devices place a micro-bend in the cable, leaking a small amount of light through the polymer cladding. Once the light signal has been accessed, the data is captured using a photo detectora transducer capable of translating an optical signal into an electrical signal.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

At this point, the only measure to prevent information from being pilfered off of optical wireless networks is the encryption of transmitted data. Many organizations make the mistake of encrypting the data and the transmission, which is redundant. If the data is encrypted, there is no need to spend extra money to send it through a secured tunnel. The trend is leaning toward encryption at the data layer, which reduces the latency and overhead associated with transport.

Unfortunately, optical hacks render most traditional security methodologies ineffective. Financial, health care, insurance and publicly traded companies saddled with regulatory compliance rarely consider that private and sensitive data delivered over fiber optic wireless communication systems is vulnerable to being captured through virtually undetectable hacks. Your data transmissions may have already been compromised without your being aware of it. Securing a fiber optic wireless transmission can be costly and difficult, and the bad guys, as usual, have a head start.

CHAPTER 21: INFORMATION SECURITY ESSENTIALS FOR IT MANAGERS: PROTECTING MISSION-CRITICAL SYSTEMS

Review Questions/Exercises

True/False

1. False
2. True
3. True
4. False
5. True

Multiple Choice

1. C
2. D
3. A
4. B
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Continuous monitoring determines if the complete set of planned, required, and deployed security controls within an information system or inherited by the system continue to be effective over time in light of the inevitable changes that occur. Continuous monitoring is an important activity in assessing the security impacts on an information system resulting from planned and unplanned changes to the hardware, software, firmware, or environment of operation (including threat space). IT managers' risk based decisions (security authorization decisions) should consider how continuous monitoring will be implemented organization wide as one of the components of the security life cycle.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

No. Security authorization, requires the explicit review and acceptance of risk by an IT manager on an ongoing basis. These risk based decisions are based on security control assessments and continuous monitoring activities. Continuous monitoring does not replace the security authorization requirement. Rather, continuous monitoring

is implemented as part of a holistic, risk management and (defense-in-depth) information security strategy that is integrated into enterprise architectures and system development life cycles. The continuous monitoring program, developed and implemented by an organization as a component in the security life cycle based approach, becomes a consideration in the risk based decisions (security authorization decisions) rendered by IT managers. Continuous monitoring also supports the requirement for conducting assessments of security controls with a frequency depending on risk, but no less than annually.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Continuous monitoring in and of itself, does not provide a comprehensive, enterprise-wide risk management approach. Rather, it is a key component in the risk management process. The fundamental tenet of a unified information security framework is an enterprisewide risk management approach to information security that is life cycle-based and implemented across three hierarchical tiers within an organization (governance, mission/business process, and information system). The ongoing determination and acceptance of information system security-related risks remains the primary responsibility of IT managers' and for which they are held accountable. Continuous monitoring activities contribute to helping IT managers' make better risk-based decisions, but do not replace the security authorization process.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Front-end security, exemplified by security categorization, security control selection, and implementation, focuses on building security into information technology products and systems early in the system development life cycle. The initial steps are also linked to the organization's enterprise architecture and information security architecture. Better front-end security results in fewer weaknesses and deficiencies in information systems, directly translating to a lesser number of vulnerabilities that can be exploited by threat sources. Back-end security, exemplified by security control assessment, information system authorization, and continuous monitoring, focuses on the effectiveness of the implemented security controls, the determination and acceptance of risk, and the ongoing monitoring of the security state of the information system.

CHAPTER 22: SECURITY MANAGEMENT SYSTEMS

True/False

1. True
2. True
3. False
4. True
5. False

Multiple Choice

1. C
2. D
3. E
4. A
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Certification of a security management system (SMS) brings several advantages. It gives an independent assessment of your organization's conformity to an international standard that contains best practices from experts for SMS. A certified SMS does not guarantee compliance with legislative and local policies, but provides a systematic platform to build on.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

ISO/IEC 27001 (BS 7799-2) is aligned with both the ISO 9001 (quality management systems) and ISO 14001 (environmental management systems) standards. The three standards share system elements and principles, including adopting the PLAN, DO, CHECK, ACT cyclic process. This approach makes it possible to integrate the systems to the extent it makes sense.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

If information assets are important to an organization's business, it should consider implementing an SMS in order to protect those assets within a sustainable framework. If an organization implements an SMS, it should consider going through the process to be certified against the ISO/IEC 27001 standard. ISO/IEC 27001 and BS 7799 continues to build a reputation for helping to model business practices that enhance an organization's ability to protect its information assets. A growing number of organizations around the world have already gone through the certification process.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Selecting the right set of controls requires the use of a risk assessment-based approach. This approach is a mandatory part of the PLAN (identify, analyze and evaluate the risks), DO (select, implement, and use controls to manage the risks to acceptable levels), CHECK, and ACT cyclic process defined in BS 7799-2 for the establishment, implementation, and maintenance of an SMS.

CHAPTER 23: POLICY-DRIVEN SYSTEM MANAGEMENT

Review Questions/Exercises

True/False

1. False
2. False
3. True
4. True
5. False

Multiple Choice

1. B
2. C
3. C
4. A
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The speed of implementation is driven by

1. The client's commitment and available resources.
2. The size and complexity of the organisation.
3. The policies and procedures already in place.

Many certification/**accreditation** bodies require at least 3 months of the management system running, in order to have enough genuine records to audit. The date of the final certification audit can depend on the availability of the external auditors, so it is an advantage to start talking to the certification body in advance.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The certification body will agree a "certification cycle". This involves a re-certification and interim surveillance audits. For example, an ISO 27001 Information Security Management system is usually re-certified every 3 years, with interim surveillance audits every 6 months from certification.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Risk can not be eliminated, only reduced and an audit is a sampling process. Auditors understand this and if they do come across an inconsistency, they may extend their sampling to establish if it is a "major break down of the management system" or a rare occurrence. Don't forget, auditors will be watching what is happening in your organization while they are there, so it's important that you deal with any day to day issues appropriately.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Auditors can raise non-conformances against the standard or the process/procedures of your organization. A

minor non-conformance will be noted if a deficiency has been found, providing it hasn't shown a serious break down in the system. The auditor will set a deadline for any minor non-conformances to be corrected and may require some evidence of this before awarding a certificate. A major non-conformance is more serious and will lead to the application for certification to be refused. These usually occur when an aspect required by the standard has not been implemented, or it has been implemented to the extent it does not meet it's objective.

CHAPTER 24: INFORMATION TECHNOLOGY SECURITY MANAGEMENT

5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Business continuity planning provides a quick and smooth restoration of operations after a disruptive event. Business continuity planning is a major component of risk management and includes business impact analysis, business continuity plan (BCP) development, testing, awareness, training, and maintenance.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Legal and regulatory requirements say at least annually. However, all organizationsshould closely monitor their critical business environments for changes and issue updates as needed.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Functions should be considered critical if any of the following apply:

- Support primary mission statement
- Support other organizations' mission critical function
- Must be recovered quickly
- Have a high dollar value
- Have a high business impact
- Have political ramifications or implications
- Have legal requirements or liabilities

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Certification of an IT security management system (ITSMS) brings several advantages. It gives an independent assessment of your organization's conformity to an international standard that contains best practices from experts for ITSMS. A certified ITSMS does not guarantee compliance with legislative and local policies, but provides a systematic platform to build on.

CHAPTER 25: ONLINE IDENTITY AND USER MANAGEMENT SERVICES

1. False
2. True
3. True
4. False
5. False

Multiple Choice

1. E
2. A
3. B
4. C
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The term digital identity is used to describe the combination of validating your identity through prescribed vetting and proofing procedures and once completed, issue a digital certificate to be used as a representation of your identity in the digital world. Digital certificates give individuals, corporations and governments the ability to prove that they are who they say they are in an electronic environment. Digital certificates will give individuals acting on behalf of a corporation or government the ability to:

- Authenticate themselves – proving in a binding, non-repudiable fashion that they are who they say they are.
- Protect information – allowing them to lock down documents or material being sent electronically so that it cannot be tampered with or viewed without their permission
- Digitally sign – allowing them to replace ink signatures with an electronic signature that is the legal equivalent and that is accepted around the globe

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

In terms of managing identities, whether digital or physical, banks are uniquely positioned as providers. The reasons:

- Banks have always played the role of trusted intermediaries for financial transactions, whether on a consumer or corporate level In terms of managing identities, whether digital or physical, banks are uniquely positioned as providers
- Banks are regulated, operating under independent oversight where failure to comply leads to serious financial implications and thus creating a strong incentive to behave properly
- Banks exist everywhere, with a broad reach into even the smallest town or location, and are subject to global requirements that ensure consistency across multiple legal or regulatory jurisdictions
- Banks have experience in dealing with information that needs to be managed carefully
- Some banks have a global scale and a scalable information systems infrastructure to support large volumes of transactions
- Banks have experience in dealing with risk management and mitigation - they are fundamentally in the business of transferring and managing risk, which makes them uniquely positioned to price and manage the risk elements of identity

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The digital identity does not capture the physical signature of the signer but instead imprints an electronic identifier, known as a private key, unique to the individual signing the transaction. Moreover, thanks to the legal and operational framework surrounding the issuance and management of the digital identities, digital signatures are legally binding, just like wet ink signatures.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

In your organization, you may have many types of digital credentials. A digital credential is a proof of qualification, competence, or clearance that is attached to a person and can encompass many forms of authentication (username/password, one-time passwords, smart cards or internally-issued digital certificates) into enterprise systems, such as business applications, online portals, Network Operating Systems, etc. The levels of identity assurance and federation that these internally issued digital credentials can convey, starts to become in question in the context of B2B transactions, particularly those of high sensitive natures (such as financial transactions). In such cases, an interoperable, bank-issued digital identity is an ideal solution to enable the B2B electronic workflow.

CHAPTER 26: INTRUSION DETECTION AND PREVENTION SYSTEMS

Review Questions/Exercises

5. True

Multiple Choice

1. B
2. C
3. D
4. A
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Intrusion detection systems are made up of three functional components, information sources, analysis, and response. The system obtains event information from one or more information sources, performs a pre-configured analysis of the event data, and then generates specified responses, ranging from reports to active intervention when intrusions are detected.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Each security protection serves to address a particular security threat to a system. Furthermore, each security protection has weak and strong points. Only by combining them (this combination is sometimes called *security in depth*) do organizations protect from a realistic range of security attacks. Firewalls serve as barrier mechanisms, barring entry to some kinds of network traffic and allowing others, based on a firewall policy. IDSs serve as monitoring mechanisms, watching activities, and making decisions about whether the observed events are suspicious. They can spot attackers circumventing firewalls and report them to system administrators, who can take steps to prevent damage.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

There are many ways of describing IDSs. The primary descriptors are the system monitoring approaches, the analysis strategy and the timing of information sources and analysis. The system monitoring approaches are network-based, host-based, and applications-based. The analysis strategies are misuse detection and anomaly detection. The timing categories are interval-based (or batch mode) and real-time. The most common commercial IDSs are real-time network-based systems.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The best IDS for your organization is the IDS that best satisfies the security goals and objectives of your organization, given the constraints of the organization. Governing factors are usually defined as the following:

- System environment, in terms of hardware and software architectures.
- Security environment, in terms of policy, existing security mechanisms, and constraints.
- Organizational goals, in terms of functional goals of the enterprise (for instance, e-commerce organizations might have different goals and constraints from manufacturing organizations).
- Resource constraints, in terms of acquisition, staffing, and infrastructure.

CHAPTER 27: TCP/IP PACKET ANALYSIS

3. True
4. False
5. True

Multiple Choice

1. C
2. C
3. C
4. C
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Detecting crashed systems over TCP/IP is difficult. TCP doesn't require any transmission over a connection if the application isn't sending anything, and many of the media over which TCP/IP is used (Ethernet) don't provide a reliable way to determine whether a particular host

is up. If a server doesn't hear from a client, it could be because it has nothing to say, some network between the server and client may be down, the server or client's network interface may be disconnected, or the client may have crashed. Network failures are often temporary (a thin Ethernet will appear down while someone is adding a link to the daisy chain, and it often takes a few minutes for new routes to stabilize when a router goes down) and TCP connections shouldn't be dropped as a result.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:
The OSI - Open System Interconnection and the TCP/IP - Transmission Control Protocol/ Internet Protocol.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Each application running over TCP or UDP distinguishes itself from other applications using the service by reserving and using a 16-bit port number. Destination and source port numbers are placed in the UDP and TCP headers by the originator of the packet before it is given to IP, and the destination port number allows the packet to be delivered to the intended recipient at the destination system.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

TCP/IP is a protocol stack used for data transmission from source to destination. In the physical layer, all the physical connections like LAN cards, cables etc., will be there; which will send data in the form of bits. Layer 2, operates with frames where the switches come into picture in the network layer, which operates on packets. The routing then takes place; and, routers are the devices used for this. The transport layer is above the network layer and it uses mainly TCP/ UDP for transport of data. The application layers is on top of this layer.

CHAPTER 28: THE ENEMY (THE INTRUDER'S GENESIS)

Review Questions/Exercises

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Download IP-Tools and install it:

The purpose of this exercise is to let the student down load the freely available software IP-Tools. This software is very easy to use and explore the concepts presented in this chapter.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Download LANguard N.S.S. (Commercial grade Network Security Scanner, N.S.S.):

The purpose of this project is to have the student download a commercial scanner with lots of options. The network should be connected to the Internet so that the students can use the Whois option and discover the name servers for a given Internet domain. This step amounts to network mapping.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Using LANguard software to Enumerate the computers in your Windows domain:

In this project students will learn about enumeration, and what information does it provide to a would be hacker. A screen-shot is displayed in the file ch04_artmsprj_au1st as Enumerate Computers.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:
Using any of the search engines on the Internet, search for the keyword as "Packet Crafting" for Windows based software, and Packet Generation under Linux.

CHAPTER 29: FIREWALLS

Review Questions/Exercises

3. False
4. False
5. False

Multiple Choice

1. D
2. D
3. A
4. A
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

A firewall policy defines how an organization's firewalls should handle inbound and outbound network traffic for specific IP addresses and address ranges, protocols, applications, and content types based on the organization's information security policies. Organizations should conduct risk analysis to develop a list of the types of traffic needed by the organization and how they must be secured—including which types of traffic can traverse a firewall under what circumstances. Examples of policy requirements include permitting only necessary Internet Protocol (IP) protocols to pass, appropriate source and destination IP addresses to be used, particular Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) ports to be accessed, and certain Internet Control Message Protocol (ICMP) types and codes to be used. Generally, all inbound and outbound traffic not expressly permitted by the firewall policy should be blocked because such traffic is not needed by the organization. This practice reduces the risk of attack and can also decrease the volume of traffic carried on the organization's networks.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

There are many considerations that organizations should include in their firewall selection and planning processes. Organizations need to determine which network areas need to be protected, and which types of firewall technologies will be most effective for the types of traffic that require protection. Several important performance considerations also exist, as well as concerns regarding the integration of the firewall into existing network and security infrastructures. Additionally, firewall solution design involves requirements relating to physical environment and personnel as well as consideration of possible future needs, such as plans to adopt new IPv6 technologies or virtual private networks (VPN).

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Firewall rulesets should be as specific as possible with regards to the network traffic they control. To create a ruleset involves determining what types of traffic are required, including protocols the firewall may need to use for management purposes. The details of creating rulesets vary widely by type of firewall and specific products, but many firewalls can have their performance improved by optimizing firewall rulesets. For example, some firewalls check traffic against rules in a sequential manner until a match is found; for these firewalls, rules that have the highest chance of matching traffic patterns should be placed at the top of the list wherever possible.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

There are many aspects to firewall management. For example, choosing the type or types of firewalls to deploy and their positions within the network can significantly affect the security policies that the firewalls can enforce. Policy rules may need to be updated as the organization's requirements change, such as when new applications or hosts are implemented within the network. Firewall component performance also needs to be monitored to enable potential resource issues to be identified and addressed before components become overwhelmed. Logs and alerts should also be continuously monitored to identify threats—both successful and unsuccessful. Firewall rulesets and policies should be managed by a formal change management control process because of their potential to impact security and business operations, with ruleset reviews or tests performed periodically to ensure continued compliance with the organization's policies. Firewall software should be patched as vendors provide updates to address vulnerabilities.

CHAPTER 30: PENETRATION TESTING

Review Questions/Exercises

True/False

1. False
2. True
3. True
4. True
5. True

Multiple Choice

1. E
2. C
3. C
4. B
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

- How well the system tolerates real world-style attack patterns.
- The likely level of sophistication an attacker needs to successfully compromise the system.
- Additional countermeasures that could mitigate threats against the system.
- Defenders' ability to detect attacks and respond appropriately.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

- **Host name and IP address information** can be gathered through many methods, including DNS interrogation, InterNIC (WHOIS) queries, and network sniffing (generally only during internal tests)
- **Employee names and contact information** can be obtained by searching the organization's Web servers or directory servers
- **System information, such as names and shares** can be found through methods such as NetBIOS enumeration (generally only during internal tests) and Network Information System (NIS) (generally only during internal tests)
- **Application and service information**, such as version numbers, can be recorded through banner grabbing.

In some cases, techniques such as dumpster diving and physical walkthroughs of facilities may be used to collect additional information on the targeted network, and may also uncover additional information to be used during the penetration tests, such as passwords written on paper.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

- **Misconfigurations**. Misconfigured security settings, particularly insecure default settings, are usually easily exploitable.
- **Kernel Flaws**. Kernel code is the core of an OS, and enforces the overall security model for the system—so any security flaw in the kernel puts the entire system in danger.
- **Buffer Overflows**. A buffer overflow occurs when programs do not adequately check input for appropriate length. When this occurs, arbitrary code can be introduced into the system and executed with the privileges—often at the administrative level—of the running program.
- **Insufficient Input Validation**. Many applications fail to fully validate the input they receive from users. An example is a Web application that embeds a value from a user in a database query. If the user enters SQL commands instead of or in addition to the requested value, and the Web application does not

filter the SQL commands, the query may be run with malicious changes that the user requested—causing what is known as a SQL injection attack.

- **Symbolic Links**. A symbolic link (symlink) is a file that points to another file. Operating systems include programs that can change the permissions granted to a file. If these programs run with privileged permissions, a user could strategically create symlinks to trick these programs into modifying or listing critical system files.
- **File Descriptor Attacks**. File descriptors are numbers used by the system to keep track of files in lieu of filenames. Specific types of file descriptors have implied uses. When a privileged program assigns an inappropriate file descriptor, it exposes that file to compromise.
- **Race Conditions**. Race conditions can occur during the time a program or process has entered into a privileged mode. A user can time an attack to take advantage of elevated privileges while the program or process is still in the privileged mode.
- **Incorrect File and Directory Permissions**. File and directory permissions control the access assigned to users and processes. Poor permissions could allow many types of attacks, including the reading or writing of password files or additions to the list of trusted remote hosts.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Penetration test scenarios should focus on locating and targeting exploitable defects in the design and implementation of an application, system, or network. Tests should reproduce both the most likely and most damaging attack patterns—including worst-case scenarios such as malicious actions by administrators. Since a penetration test scenario can be designed to simulate an inside attack, an outside attack, or both, external and internal security testing methods are considered. If both internal and external testing is to be performed, the external testing usually occurs first.

Outsider scenarios simulate the outsider-attacker who has little or no specific knowledge of the target and who works entirely from assumptions. To simulate an external attack, testers are provided with no real information about the target environment other than targeted IP addresses or address ranges, and perform open source research by collecting information on the targets from public Web pages, newsgroups, and similar sites. Port scanners and vulnerability scanners are then used to identify target hosts. Since the testers' traffic usually goes through a firewall, the amount of information obtained from scanning is far less than if the test were undertaken from an insider perspective. After identifying hosts on the network that can be reached from outside, testers attempt to compromise one of the hosts. If successful, this access may then be used to compromise other hosts that are not generally accessible from outside the network. Penetration testing is an iterative process that leverages minimal access to gain greater access.

Insider scenarios simulate the actions of a malicious insider. An internal penetration test is similar to an external test, except that the testers are on the internal network (behind the firewall) and have been granted some level of access to the network or specific network systems. Using this access, the penetration testers try to gain a greater level of access to the network and its systems through privilege escalation. Testers are provided with network information that someone with their level of access would normally have—generally as a standard employee, although depending on the goals of the test it could instead be information that a system or network administrator might possess.

Penetration testing is important for determining the vulnerability of an organization's network and the level of damage that can occur if the network is compromised. It is important to be aware that depending on an organization's policies, testers may be prohibited from using particular tools or techniques or may be limited to using them only during certain times of the day or days of the week. Penetration testing also poses a high risk to the organization's networks and systems because it uses real exploits and attacks against production systems and data. Because of its high cost and potential impact, penetration testing of an organization's network and systems on an annual basis may be sufficient. Also, penetration testing can be designed to stop when the tester reaches a point when an additional action will cause damage. The results of penetration testing should be taken seriously, and any vulnerabilities discovered should be mitigated. Results, when available, should be presented to the organization's managers. Organizations should consider conducting less labor-intensive testing activities on a regular basis to ensure that they are maintaining their required security posture. A well-designed program of regularly scheduled network and vulnerability scanning, interspersed with periodic penetration testing, can help prevent many types of attacks and reduce the potential impact of successful ones.

CHAPTER 31: BUILDING A SECURE ORGANIZATION

Review Questions/Exercises

2. True

3. False
4. False
5. True

Multiple Choice

1. A
2. A
3. D
4. C
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

When a vulnerability is exploited the impact will be a security violation. Denial of Service (DoS) and Privilege escalation are two dangerous impacts. Vulnerabilities are exploited by Malware such as viruses, trojan horses, worms, spyware and so on. Malicious hackers compromise the systems through vulnerability exploitation

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The default scanning process will not have any impact on your server resources. However, when a scanning is performed with custom options such as scanning all the ports or scanning by connecting to the ports, there will be very low impact on performance. You can assigh a custom scan timings such as out-of-office hours to perform such resource intensive scans.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Open Vulnerability and Assessment Language (OVAL®) is an international, information security, community standard to promote open and publicly available security content, and to standardize the transfer of this information across the entire spectrum of security tools and services. OVAL includes a language used to encode system details, and an assortment of content repositories held throughout the community. The language standardizes the three main steps of the assessment process: representing configuration information of systems for testing; analyzing the system for the presence of the specified machine state (vulnerability, configuration, patch state, etc.); and reporting the results of this assessment. The repositories are collections of publicly available and open content that utilize the language.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

OVAL itself is not a vulnerability scanner. Rather, it is an open language to express checks for determining whether software vulnerabilities—and configuration issues, programs, and patches—exist on a system. OVAL allows the sharing of technical details regarding how to identify the presence or absence of vulnerabilities on a computer system. The public nature of OVAL provides computer security researchers, software vendors, and system administrators with the means to collaborate to develop OVAL definitions. The end user of an OVAL-compliant tool benefits from this collaboration because of increased quality from the number of experts participating in the development of definitions, and now has the option of personally reviewing the individual definitions to see exactly how the vulnerability determination was made. This is in direct contrast to closed, proprietary methods of vulnerability assessment.

CHAPTER 32: SECURITY METRICS: AN INTRODUCTION AND LITERATURE REVIEW

1. C
2. D

3. A
4. D
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

There are *loads* of sources of inspiration if you are hunting for security metrics. For now, here is a shortlist: Consider existing security metrics, or indeed other kinds of metrics already used by your organization. Use standards such as ISO/IEC 27004 (not the best example, admittedly!) Take advice from professional bodies such as ISACA and the Information Security Forum. Use your social networks: ask professional colleagues and peers, raise metrics at the next ISSA meeting or security conference, or discuss it online! Finding possible metrics (information-security-related things that could be measured) is very much the easy part. Deciding which of the thousands of candidate security metrics are actually worth measuring, reporting and using is a different matter entirely.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Reporting security metrics often implies a rather tedious written management report stuffed with graphs and tables, but there are sound reasons for being far more creative in your approach. For a start, think about who you are reporting *to*. What do *they* want from you? What type or types of communication do *they* prefer - written reports with all the gory details, short executive summaries, web pages, presentations, rough notes discussed over coffee or something else?

Often it is better to discuss security metrics with the recipients rather than simply submitting a report. Discussion gives everyone the chance to explain things, ask questions, provide feedback, and generally mull over the information. Given that the prime purpose of metrics is for decision support, discussion and persuasion seems far more likely to facilitate sensible decisions than passively providing written information in a report, although it makes sense to provide the figures, graphs *etc.* on paper or on screen as well as discussing them - the best of both worlds.

A bonus to presenting and discussing security metrics is the opportunity to get instant feedback on the metrics themselves, and to make sure that everyone understands exactly what is being measured, why and how if necessary. Simple security metrics are generally self-evident but more complicated or convoluted ones deserve and may in fact *require* explanation.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Metrics that are *inherently* bad (in the sense of having low scores, low utility, low value) should not be used. If however the measurements themselves - the *numbers* - are bad, that is a different matter entirely.

Good metrics sometimes do show bad numbers for two reasons: either the subjects of measurement have turned bad in some measurable way (for example, the actual rate and/or severity of security incidents has markedly increased) or the measurement process has gone wrong (for example, security incidents are occurring at about the same rate as ever but the *reporting* of incidents has dramatically improved, or new sources of information such as additional classes of incident reports have been incorporated into the metric). Either way, that is potentially useful information provided it can be explained and understood - and to do that will probably require additional analysis and information. This is where the ability to dig deeper, going beneath the headline figures to identify the specific factors involved, pays off. Interpreting security metrics combines science with art!

Reporting really bad numbers may not seem a sensible move - indeed, in extreme cases, it could be career-limiting. On the other hand, *not* reporting those numbers could have severe if the information in question, or the fact that it was withheld, eventually comes out. On top of that, the recipients of metrics may well smell a fish if a regular report is late or doesn't show up, or the figures appear suspiciously good, or the written analysis and/or verbal description paint a rosier picture than the numbers (discordant reporting). It takes guts to report really bad numbers.

Just remember that bad numbers focus attention on issues and present improvement opportunities. Good numbers tend to just wash over us, having little impact and hence limited information value. In fact, the most useful metrics tend to highlight and provide some explanation

for *changes* in values rather than absolute numbers. If the numbers are consistently good, why bother reporting them when there are doubtless other issues that deserve attention? [This is a common complaint about those voluminous Service Level Accounting reports often delivered by service providers to their customers. Is the real reason why so many numbers are presented simply to hide or divert attention from the few bad ones?]

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

While decisions *can* be made on a whim, many business decisions have serious consequences, hence the risk of making wrong decisions, or indeed not making necessary decisions in time, can be substantial. Gathering and assessing information that is relevant and timely for a decision could therefore be deemed a risk management activity, and naturally metrics are a key source of relevant information.

Consider for example the use of Ishikawa (fishbone) diagrams in quality assurance and process engineering to assess the factors that contribute to or cause some effect on a process. While approaches vary, a popular method involves analyzing the possible causes of a problems on a process along six lines radiating out from the backbone, each covering one of the **M**s:

- **Manpower**: the people performing activities - are they suitably trained and competent? Are they over- or under-worked? Are they well motivated and energetic?
- **Machines**: including machine tools, computer systems *etc*. - are they working efficiently and effectively? Are they functional and reliable?
- **Materials**: raw materials, supplies and other process inputs - are they of suitable quantity, quality and reliability? Do they always arrive in time or sometimes cause delays? Are they within specifications?
- **Methods**: how people use the machines to perform activities on the materials- are they doing the right things, and doing things right? Are the procedures suitable and efficient, or are there better ways?
- **Mother Nature** (the **Mvironment**): the surroundings in which activities are performed - are they conducive to good work? Is the workplace comfortable and safe, or is it an impediment?
- **Metrics**: measures relating to the process - do we know what is going on and what might be going wrong? Do we have the information necessary to plan, direct, control and improve the process?

Security metrics, then, provide information about the people, the machinery, the inputs, the processes, and the environment, both statically (in planning/designing the process, or reviewing the start-of-day situation in a morning quality meeting) and dynamically (monitoring and where necessary adjusting the process during the course of the day according to events and feedback). Security metrics don't replace the other **M**s - they complement and support them, enabling management to get more out of the available resources and cope with perturbations. Just as importantly, security metrics don't exist in isolation. They have negligible inherent value (information that is just nice-to-know) but immense value for managing business (or indeed other) activities. They have a purpose in life.

CHAPTER 33: CYBER FORENSICS

Review Questions/Exercises

True/False

1. True
2. False
3. True
4. False
5. True

Multiple Choice

1. D
2. D
3. C
4. C
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The vast majority of documents now exist in electronic form. No investigation involving the review of documents, either in a criminal or corporate setting, is complete without including properly handled computer evidence. Cyber forensics ensures the preservation and authentication of cyber data, which is fragile by its nature and can be easily altered, erased, or subject to claims of tampering without proper handling. Additionally, cyber forensics greatly facilitates the recovery and analysis of deleted files and many other forms of compelling information normally invisible to the user.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Most recoveries will be completed in 1–4 days. If you need e*xpedited data recovery*, you'll need a dedicated technician assigned to your drive within 3 hours of the time that you send in your hard disk. This process will normally cut your turnaround time in half. However, if you need e*mergency data recovery*, you will need to make arrangements for a technician to be available who will be assigned to work on your recovery until complete. The goal here is to return your data to you within two to four working days. However, because of the complexity of data recovery, there will be times when it will take longer.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

There are instances where the damage to the hard drive is so severe that data recovery is not possible. This usually occurs when the read/write heads actually "crash" and gouge the magnetic storage media to the point where the data is destroyed.

However, in a number of cases, data recovery was possible at the time the damage first occurred, but the data became nonrecoverable through the use of commercial-recovery software. This software is designed to recover data from working drives. If your drive has experienced a mechanical or electrical failure, the use of recovery software can cause permanent loss of your data.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Avoid Heat and Vibration
All drive components, both electronic and mechanical, are sensitive to heat and vibration. Keep your computer in a dry, controlled environment that is clean and dust-free. Set up your computer in an area with little traffic to ensure that it does not get bumped. Heat and/or vibration are two of the leading causes of hard drive failure. Also, beware of static.

Back-Up Your Data
The surest way to avoid data loss, even if your hard drive fails, is to back-up your data. If you don't have a tape back-up device or network drive at your fingertips, back-up your most important files at least once a week.

To Avoid Premature Drive Failure,Run Scandisk
Scandisk examines your hard disk for logical inconsistencies and damaged surfaces. Run it every two or three weeks just to be safe. It is important to save any changes until you are sure that the changes you are about to make will not adversely affect your hard drive.

Run Defrag Frequently
Files will most likely not be stored in adjacent clusters. Defrag rearranges the data on your hard disk so that each file is stored in a set of contiguous clusters. This is essential for data recovery because success is more likely when the damaged file's clusters are adjacent to each other.

Antivirus Software
Use antivirus software and update it at least four times a year. Also, use an uninterrupted power supply (UPS).

In the event of a surge of electricity, black out, brown out, or lightning strike, a UPS can protect your system from electrical damage. A UPS is also a back-up power source that keeps your computer running for a short period of time, giving you the opportunity to properly save your work and shut down, avoiding a potential data loss.

Be Cautious When Using Recovery Utilities
Use diagnostic and repair utilities with caution. Verify that your utility software is compatible with your operating software. Never use file-recovery software if you suspect an electrical or mechanical drive failure. Always make an undo disk when you allow a utility to make changes to your hard drive.

CHAPTER 34: CYBER FORENSICS AND INCIDENT RESPONSE

Review Questions/Exercises

3. D
4. D
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

It is extremely important that your hard drive is packaged carefully—to avoid any additional damage during shipment. Only your drive is required for data recovery.

Packaging the Hard Drive
Wrap the hard drive in an antistatic material. If an antistatic bag is not available, a freezer bag will suffice. It is recommended that you ship the drive in its original manufacturer's packaging. If this is not possible, pack the hard drive in a sturdy corrugated cardboard box twice the size of the drive, with heavy foam padding, bubble wrap, or other antivibration materials. Do not use Styrofoam peanuts as they attract static electricity. Be sure the padding material is at least two inches thick around the drive.

Water-Damaged Hard Drives
If your drive has suffered water damage, please do not dry it. Enclose the drive along with a damp sponge in a sealed plastic bag to prevent it from drying out.

Controller Boards
When recovering from older models, you may need to send the controller along with the drive. Please remove the controller carefully, enclose in antistatic material, and ship it along with the drive.

Other
Please package all other types of media, following the guidelines in the preceding for a typical hard drive.

Locations

Ship the drive directly to the recovery facility nearest you: It is recommended that you ship via UPS or Federal Express domestically and internationally, using next-day service. If you elect to use another carrier, it is suggested that you use an overnight service. Also, if you have any special shipping considerations, questions, or concerns, please contact your overnight carrier

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:
If your drive is repairable, the repair will be completed and your data returned to you on your original drive. When your data is recovered and your drive is not repairable, there are many different ways to return your data.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:
There are no answers for this case project. It's just an exercise that students will go through to gain experience.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

As soon as possible. While CSI and other forensic television shows primarily provide entertainment, they also accurately emphasize that time is critical for an investigation. The longer a computer or digital device is used or awaits inspection, the higher the probability that the digital evidence will be tainted. Even for computers in storage awaiting discovery for trial, the sooner a computer forensic examiner can preserve the valuable data, the greater the chance of recovering important and relevant evidence.

CHAPTER 35: SECURE E-DISCOVERY

4. True
5. False

Multiple Choice

1. D
2. D
3. C
4. A
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Although internal IT staff are often highly knowledgeable regarding their working environment and the technology employed within, computer forensic investigations

are best performed by outside experts. Specifically, the nature of the forensic analysis process coupled with the requirements by law enforcement agencies and the court system necessitates that computer forensic investigations are performed by external entities equipped with authorized forensic technology and trained to observe forensic protocols. Forensic specialists:

- Employ the proper hardware and software to identify, isolate, and preserve electronic information in a court admissible manner
- Possess the expertise and experience vital to efficiently analyze electronic information and uncover electronic evidence
- Rely upon essential training and experience to ensure the court admissibility of electronic evidence
- Offer truly objective expert testimony that only a third-party computer forensic investigator can
- Expose flaws in opposing counsel's interpretation of electronic evidence and results from their forensic analysis efforts

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

A common misconception is that when information or a specific file is deleted, it is permanently erased from the hard drive. In reality, the act of deleting a file does not actively delete any information. What occurs is a small portion of information that points to the location of the file on the hard drive is erased.

This pointer is used by the operating system to compile the directory tree structure and by removing this pointer file, the actual file becomes invisible to the operating system. Overtime, the location of the unwanted file will be overwritten by new information. Forensic technology exists to locate, reconstruct, and recover information and files that were deleted, however, still exist in total or have been partially overwritten by new data.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

The fragile and volatile nature of electronic information requires orchestrated efforts to ensure electronic evidence is protected and maintained to facilitate its thorough analysis by a computer forensic specialist and its introduction into an active litigation. Internal technology relevant to an investigation or litigation should be immediately removed from operation and isolated from unauthorized use with a clearly documented chain of custody agreement to ensure electronic evidence is not unintentionally corrupted or overwritten.

If relevant technology is under the management of opposing counsel, a notification of the duty to preserve electronic evidence should be transmitted. This letter should detail the information to be preserved, potential locations of suspect information, listing of people that may have access to the technology, and all potential storage media where the information may reside, such as hard drives, CD-ROMs, and backup tapes. If necessary, an injunction or preservation order forbidding the deletion or manipulation of electronic information can be obtained.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

Spoliation is the intentional or negligent destruction or alteration of evidence when there is current litigation or an investigation or there is reasonable anticipation that either may occur in the near future. Some jurisdictions also define it as a failure to preserve information that may become evidence. To address spoliation and minimize threats to the forensic integrity of electronic evidence and its admissibility in a litigation, technology potentially containing electronic evidence must be handled methodically and in response to the fragile and volatile nature of electronic information.

When litigation arises, corporate counsel needs to think both offensively and defensively about managing electronic evidence. Preservation memos should be sent to all employees who have potentially relevant data, specifically identifying each type of system records that may have relevance to the case. Monitoring preservation compliance is extremely important to avoid spoliation sanctions. Technology relevant to an investigation or litigation should be immediately removed from operation and isolated from unauthorized use with a clearly documented chain of custody agreement to ensure electronic evidence is not unintentionally corrupted or overwritten. Furthermore, the nature of the forensic analysis process coupled with the requirements by law enforcement agencies and the court system necessitates that computer forensic investigations are performed by certified experts equipped with authorized forensic technology and trained to observe forensic protocols to greatly reduce the risk of

error, omission, or direct damage to the forensic integrity of electronic evidence.

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

With a network forensics analysis, data is always available for reconstruction, with an easy analysis of intermittent issues, cyber attacks, and network security or data breaches. All pertinent network traffic is collected in a single location, rather than scattered across the network. Data is captured in a common data format and does not need to be transferred or translated in any way for analysis.

Using network forensics data mining tools, network engineers have the data they need to identify and fix problems users are complaining about that only occur intermittently, and security teams can reconstruct the sequence of events that occur at the time of a network breach or cyber attack and get the complete picture. Network forensics data mining tools, will enable you to analyze data at the point of capture, and eliminate the need for large data transfers that consume time and bandwidth.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

24×7 access to all network data and network forensics mining tools lets an organization do the following:

- Ensure network and security data are captured 24×7 and not sacrificed when SPAN ports are needed for other applications
- Reduce Mean-Time-To-Resolution (MTTR) by eliminating the time consuming step of having to reproduce problems before they can be analyzed and responding to issues in real-time, often solving issues before mission critical applications are impacted
- Understand service-level compliance within your organization
- Comply with government regulations and Human Resources policies by auditing and tracking all network activity

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

A network forensics analysis solution offers the following capabilities:

- **Comprehensive data collection:** Hours or even days of network traffic —anything that crosses the network, whether email, IM, VoIP, FTP, HTML, or some other application or protocol — collected by a single system and stored in a common, searchable format. Terabytes of data are available through a single interface.
- **Flexible data collection:** Collects all data on a network segment for future inspection or focus on a specific user or server.
- **High-level analysis:** Eliminates the need for brute-force analysis across disparate data sources.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

- Network performance benchmarking for detailed reporting on network performance, bottlenecks, activates, etc.
- Network troubleshooting for handling any type of network problem, especially those that happen intermittently.
- Transactional analysis for providing the “ultimate audit trail” for any transactions where server logs and other server-based evidence doesn’t provide a thorough picture of a transaction. Remember, packets don’t lie!

- Security attack analysis for enabling security officers and IT staff to characterize and mitigate an attack that slipped past network defense such as a zero day attack.

Intermittent Issues

- Capture and analyze intermittent network problems
- Troubleshoot problems that occurred hours or days ago
- Find the patterns that ad hoc, reactive troubleshooting will miss

Security Cyber Attack Analysis

- Detect and characterize attacks—whether they've just begun or occurred days ago
- Apply filters to isolate malicious behavior
- Equip your network IT team with a powerful incident response tool

Transaction Analysis

- Create the ultimate audit trail for business transactions—not just server activity but the business transactions enacted by clients and servers
- Troubleshoot the transaction problems that server logs miss

CHAPTER 37: DATA ENCRYPTION

Review Questions/Exercises

True/False

1. False
2. False
3. True
4. False
5. False

Multiple Choice

1. A
2. A
3. AB
4. C
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Subsequent processing of the protected data (decryption) is accomplished using the same key as was used to protect the data. Each 64-bit key shall contain 56 bits that are randomly generated and used directly by the algorithm as key bits. The other eight bits, which are not used by the algorithm, may be used for error detection. The eight error-detecting bits are set to make the parity of each 8-bit byte of the key odd. That is, there is an odd number of "1"s in each 8-bit byte.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

A TDEA key consists of three keys for the cryptographic engine (***Key*1**, ***Key*2** and ***Key*3**); the three keys are also referred to as a key bundle (***KEY***). Two options for the selection of the keys in a key bundle are **approved**. Option 1, the preferred option, employs three unique keys (***Key*1**, ***Key*2** and ***Key*3**, where ***Key*1≠*Key*2**, ***Key*2≠*Key*3**, and ***Key*3≠*Key*1**). Option 2 employs two unique keys and a third key that is the same as the first key (***Key*1**, ***Key*2** and ***Key*3**, where ***Key*1≠*Key*2** and ***Key*3 = *Key*1**). A key bundle **shall not** consist of three identical keys.

Case Projects

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

- Be kept secret.
- Be generated using an approved method that is based on the output of an approved random bit generator.
- Be independent of other key bundles.
- Have integrity whereby each key in the bundle has not been altered in an unauthorized manner since the time it was generated, transmitted, or stored by an authorized entity.
- Be used in the appropriate order as specified by the particular mode.
- Be considered a fixed quantity in which an individual key cannot be manipulated while leaving the other two keys unchanged; and cannot be unbundled except for its designated purpose.

Optional Team Case Project

Solution

The following is a partial project solution. The students should be able to expand on the following through extensive research:

- 01010101 01010101
- FEFEFEFE FEFEFEFE

- E0E0E0E0 F1F1F1F1
- 1F1F1F1F 0E0E0E0E

CHAPTER 38: SATELLITE ENCRYPTION

Review Questions/Exercises

True/False

1. True
2. False
3. True
4. True
5. True

Multiple Choice

1. A, B
2. B
3. A
4. D
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

An encryption security team simply used generally-available phone equipment, found the crypto key and managed to break it fairly easily by analyzing the software running on the satphones.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The bank opted first for a hardware solution, but quickly realized that a software solution delivered greater long-term flexibility. Like many financial companies that take their responsibilities for data security very seriously, bank decided to encrypt their satellite data backups to protect sensitive customer and bank data. Initially, the hardware approach was attractive as it was faster, fully integrated, easy to implement and appeared to manage every part of the satellite data encryption process. However, soon after installation, the bank began to realize the disadvantages of relying primarily on a hardware solution.

As the bank began to explore satellite encryption software options, they decided to demo and compare trial versions from the market's two primary leaders. The selected solutions were roughly comparable in terms of price (which was much less than a hardware device) and functionality. They both were easy to install, configure and use. The software documentation was more detailed regarding the required steps and configuration options to implement satellite encryption into their backup routine.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

The solution is to develop an entirely new hardware platform and incorporate control software and encryption into it. The new platform should be of the kind that is widely used in commercial grade receivers in the industry.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

The company redesigned their commercial grade satellite receiver, while incorporating their encryption system at a reduced cost. They delivered over 200,000 satellite receivers and met all delivery schedules.

CHAPTER 39: PUBLIC KEY INFRASTRUCTURE

Review Questions/Exercises

True/False

1. False
2. False
3. True
4. True
5. True

Multiple Choice

1. B
2. B
3. D
4. A
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Public-key cryptography is becoming a vital business tool for any organisation that seeks to protect its information assets in potentially untrusted network environments. The use of public-key cryptography makes it possible to:

- Encrypt communications (when sending confidential e-mail over an untrusted network)
- Detect unauthorised changes to data transmitted over networks
- Positively identify and authenticate remote users over networks (when required to provide access to sensitive systems)
- Digitally sign information (when authorising services electronically and where evidential value is important)
- Ensure users cannot repudiate their actions at a later date (when required to confirm the identity of the specific user who sent a particular message or instruction over an untrusted network).

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

There are some practical problems associated with the use of public-key cryptography that, unless properly addressed, serve to undermine the above capabilities and cast doubt on the trustworthiness of any system that employs it. Foremost amongst these is the management of cryptographic keys where a lack of control could lead to the:

- Inability to update or renew keys
- Inability to recover data encrypted with an old key
- Continued use of a compromised or lapsed key.

Other considerations that arise as a consequence of using public-key cryptography include:

- Protecting public keys from impersonation and forgery
- Making public-key cryptography available to a wide number of users in a manner that is consistent and reliable
- Making public-key cryptography transparent to end-users.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

A PKI addresses these issues by:

- Managing keys throughout their life cycle
- Using digital certificates to protect and assure the authenticity of public keys
- Providing a consistent, dependable and scalable infrastructure for the use of public-key cryptography.

By providing an environment for the reliable use of authentication, confidentiality, integrity and non-repudiation services, a PKI can help to provide the trust that is necessary to conduct business in insecure networked environments.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

A typical PKI consists of seven core components. These are briefly described below:

1. Digital certificates (public-key certificates, X.509 certificates): A digital certificate is a signed data structure that binds one or more attributes of an entity with its corresponding public key. By being signed by a recognised and trusted authority (the Certification Authority) a digital certificate provides assurances that a particular public key belongs to a specific entity (and that the entity possesses the corresponding private key).
2. Certification Authority (CA): Certification Authorities are the people, processes and tools that are responsible for the creation, issue and management of public-key certificates that are used within a PKI.
3. Registration Authority (RA) : Registration Authorities are the people, processes and tools that are responsible for authenticating the identity of new entities (users or computing devices) that require certificates from CAs. RAs additionally maintain local registration data and initiate renewal or revocation processes for old or redundant certificates. They act as agents of CAs (and

in that regard can carry out some of the functions of a CA if required).

4. Certificate repository: A database, or other store, which is accessible to all users of a PKI, within which public-key certificates, certificate revocation information and policy information can be held.
5. PKI client software: Client-side software is required to ensure PKI-entities are able to make use of the key and digital certificate management services of a PKI (key creation, automatic key update and refreshment).
6. PKI-enabled applications: Software applications must be PKI-enabled before they can be used within a PKI. Typically this involves modifying an application so that it can understand and make use of digital certificates (to authenticate a remote user and authenticate itself to a remote user).
7. Policy (Certificate Policy and Certification Practice Statement): Certificate Policies and Certification Practice Statements are policy documents that define the procedures and practices to be employed in the use, administration and management of certificates within a PKI.

Under certain circumstances other PKI components may also be required, including:

- A trusted time-stamping service (where it is important to keep an accurate record of the precise timing of events).
- A Validation Authority (where automatic, real-time validation of certificates is required, for example in highly critical systems).
- A notary service (where it is important to ensure accurate records of all transactions are lodged and maintained in a secure manner, for example where the implications of a PKI user repudiating their actions would be damaging or costly).

In addition to the above components a PKI must operate within an IT infrastructure (a network with servers and client computers). This infrastructure must be able to support the processing, resilience and performance demands of a PKI.

CHAPTER 40: PASSWORD-BASED AUTHENTICATED KEY ESTABLISHMENT PROTOCOLS

Review Questions/Exercises

True/False

1. False
2. True
3. True
4. True
5. False

Multiple Choice

1. D
2. C
3. C
4. B
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

This implies that no mechanism can be in place to directly ensure at either end of the protocol that the correct password is being used by the other party. For instance, the password cannot satisfy any kind of efficiently verifiable equation, which happens to be the flaw of the dummy protocol. In contrast, this is exactly how a digital signature scheme functions, the key difference again being that the long-term secret is cryptographically strong. This is the method behind STS.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

In this work, the protocol and several of its variants have been *proven secure*(a very precise mathematical proof of security was given assuming that the encryption function satisfies some idealized properties). This is methodologically important and theoretically interesting; however, such proofs do not necessarily immediately translate into real-world security guarantees.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

As with EKE, the prime p has to be at least 1024 bits in length, so as to be sure the computing discrete logarithms will be difficult. Thus, also as in EKE, the random numbers chosen by the parties are quite large: at least 1023 bits in this case.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

The purpose of the protocol is for P to convince V that a certain statement is true without revealing any more information on that statement. For this to be of any use to V, it should be infeasible for a cheating P to trick V into believing a false statement.

CHAPTER 41: INSTANT-MESSAGING SECURITY

Review Questions/Exercises

True/False

1. True
2. False
3. True
4. False
5. True

Multiple Choice

1. C
2. D
3. C
4. C
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Fundamentally, the difference between IM and email is the notion of presence. This means that users of the IM system are aware that other users have logged in and are willing to accept messages. Unlike email, IM content can only be sent to users who are logged in to the system and accepting messages. If users are not logged in, others do not have the ability to send them messages. Because IM is not predicated upon an open standard, there is no uniformity regarding message transmission and structure.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Organizations developing a comprehensive policy need to ensure that IM content is managed consistently across the organization in its component offices. An effective policy addresses the authorized use of the IM technology and provides guidelines for the management of the records generated during an IM session. This is especially important because IM content may be subject to various types of access requests, including under the Freedom of Information Act (FOIA) or as part of a discovery process in a litigation context.

IM content that is a record must be managed as such. Here are two ways:

- Provide policies that inform users what steps to undertake to manage the content; or,
- Configure the IM client or server to capture IM without user intervention.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Nearly all IM client software has the ability to capture the content as either a plain text file or in a format native to that client. Generally, the location and maximum size of that file is determined by a configuration setting in the client. Such formats include those files produced by the various IM clients.

In addition, various IM management products have the ability to address the monitoring and management of IM content, either from those clients that are part of the agency's enterprise or the various public clients. Generally, these products operate at the server level and should be able to capture IM sessions regardless of the configuration of the individual client. Determining which solution is appropriate for your organization involves collaboration among the program staff, the information technology (IT) staff and the records management staff.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

If an organization determines IM content to be a record, the record must have an approved disposition authority. Do not identify IM content as a single series of records with a universal disposition. Instead, evaluate IM content within the context of the overall records of the program to which the IM relates and the business rules that may apply. Disposition instructions for IM should be consistent with similar organization records. Schedule in accordance with the organization 's established records

management policy. IM records may already be scheduled as part of other series, such as records typically found in a case file or a correspondence system.

CHAPTER 42: PRIVACY ON THE INTERNET

Review Questions/Exercises

True/False

1. True
2. False
3. False
4. False
5. False

Multiple Choice

1. C
2. D
3. A
4. A
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Many websites that collect personal information also publish privacy policies or privacy statements that describe how the site will use your information. Before entering any personal information into a website, you should read the privacy statement carefully, especially if you are unfamiliar with the site. Look for conditions that you do not agree with, such as allowing the website to share your information with others or the requirement that you will accept e-mail or advertising. Remember that even though the website might have a privacy statement, it doesn't mean that the website will not misuse your information. You should not give personal information to a website you do not trust.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Most online merchants use secure connections to provide an encrypted connection between Internet Explorer and the website. Encrypted connections make it difficult for a hacker to intercept your personal or financial information as it is being sent to the website. This encryption is provided by a security certificate, which is an electronic document that identifies the website. Although encryption can help protect your information as it travels over the Internet, it doesn't guarantee that the website is reputable or that they protect your information once they receive it.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Filtering can help you control whether information about the websites you visit is shared with other content providers. When you visit a website that displays content from another content provider, that content provider automatically receives some information about your visit. If you visit additional websites that have content from the same provider, that content provider can build a profile of your browsing habits. This information can be sold to other websites, or used for things such as targeted advertising.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Browsing can help you browse the web without leaving a trail on your computer while you're using the web. This can be helpful when using a public kiosk or if you don't want others who use your computer to see where you've been.

CHAPTER 43: PHYSICAL SECURITY ESSENTIALS

Review Questions/Exercises

True/False

1. True
2. False
3. False
4. False
5. True

Multiple Choice

1. E
2. D
3. A
4. A
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Cyber crime is growing and has become more organized and sophisticated. As we increasingly perform high-value transactions online such as mortgage applications, buying stocks, or reviewing health care information, our vulnerability to theft, fraud, and privacy violations increases proportionately.

Sixty years ago, before the invention of the credit card, people simply accepted the danger inherent in carrying cash with them to make a large payment. Today we accept the dangers of using easy-to-break passwords and providing personal information to dozens of different Web sites as the cost of doing business on the Internet. But we don't have to.

Privacy enhanced technologies exist now to make online transactions more secure, private, and more convenient. NSTIC offers a vision of the future where the private sector, civil societies, and the public sector collaborate to create the standards and policies needed for interoperable trusted credentials that would dramatically reduce ID theft and fraud online. In addition, by acting now and creating a more trusted environment for online transactions, we will ensure that the Internet continues to support innovation and the creation of new jobs.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

No. Like the bank card and PIN you use to obtain money from an ATM, having a password and a credential in physical form such as a cell phone, token, or smart card is much more secure than passwords alone. In addition, you may choose to have multiple credentials from different identity providers. However, even a single Identity Ecosystem credential is privacy-enhancing, because it can send different types of information to different service providers. For example, you could use your credential to log in to your online magazine subscription as "John568," because the magazine doesn't need to know your real name. But if you want to access your medical records, the same credential could prove that you are truly "John Smith."

Past experience has shown that "multi-factor authentication" is much more secure than passwords alone. For example, a bank could issue you both a physical device, such as a key fob (something you have), combined with a short PIN number (something you know) to access your accounts. This two-factor method would make it much more difficult for thieves to break into your accounts. Your cell phone could also carry a digital certificate (something you have) that requires a password (something you know).

The key is that you can have multiple trusted identity credentials, and even if you lose the physical device, a cyber criminal still can't assume your identity without your PIN or password. Having even a few PIN numbers or passwords - should you choose to use multiple credentials - would be much more convenient than the dozens of passwords most people are forced to remember now. Also, should a credential be lost, you can more easily notify all necessary parties to secure accounts through the credential provider, rather than having to notify each individually. The ID provider would then discontinue that credential and issue you a new one, helping to minimize the likelihood of unauthorized activity.

No solution, of course, is a magic fix for all possible cybersecurity risks, and NSTIC does not claim to have answers to all threats associated with online transactions. It is, however, a major step forward in making the growing number of online transactions more convenient, more secure and more private.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

One of the first actions for the National Program Office once it is established will be to convene a workshop for companies, privacy advocates, and other stakeholders to develop a steering group for the Identity Ecosystem. This group would administer the process for developing the technical standards and policies needed for the Identity Ecosystem. A community of members with similar goals and perspectives (known as a trust framework) can hold its members accountable to follow specific standards and policies. An accreditation authority would assure that individual service providers adhered to accepted Identity Ecosystem practices. Those who violate the rules would lose their trustmark status. Furthermore, the role of the government in the Identity Ecosystem is to ensure that individuals are protected from serious harm.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

New ways of conducting business in the marketplace sometimes create uncertainty. If the marketplace does not respond in a timely way to that ncertainty with ways to ensure that privacy is protected and limits on liability are described then changes to current federal laws may be necessary.

CHAPTER 44: PERSONAL PRIVACY POLICIES

Review Questions/Exercises

True/False

1. False
2. True
3. True
4. True
5. True

Multiple Choice

1. D
2. C
3. C
4. B
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

When providing copies of information for others, do employees make sure that nonessential information is removed and that personally identifiable information that has no relevance to the transaction is either removed or masked?

Are employees trained never to leave computer terminals unattended when personally identifiable information is on the screen?

Do you use password-activated screen-saver programs?

Are all employees who handle personal information—including temporary, back-up and contract staff—trained to detect when they are being "pumped" for personal information by unauthorized and unscrupulous persons? "Pretext" interviews are more common than might be expected and are the stock in trade of persons bent on finding out confidential personal information to which they are not entitled.

Do you perform background checks on prospective employees who will have access to personal information of customers, clients, or employees?

Have employees been instructed on what might constitute inappropriate use of social networking sites? Employees must be made aware of the privacy pitfalls inherent in social media. "Twittering" or "Facebooking" about sensitive work issues can have adverse consequences far beyond a simple conversation.

Have you inventoried the various types of data being stored and classified it according to how important it is and how costly it would be to the organization if it were lost or stolen?

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Does your organization have a records retention/disposal schedule for personally identifiable information, whether stored in paper, micrographic or electronic (computer) media? Customer records stored electronically or in paper files are a company asset, just like the furniture or the computers. Not only that, but customers' personal information, unlike the furniture, is subject to a myriad of laws that dictate privacy protections, safeguarding measures, and proper disposal. Even in hard times, when a company has to close its doors, customer data should never be abandoned or left at the curb for the trash collector. Such actions could subject owners, even of a defunct business, to unwanted lawsuits by customers and government regulators.

When disposing of computers, diskettes, magnetic tapes, CD-ROMs, hard drives, memory sticks, mother boards, and any other electronic media which contain personally identifiable information, are all data rendered unrecoverable by either physically destroying the device or by over-writing the data sufficiently to ensure destruction?

If you use third-party services for computer recycling or destruction, have you selected a service that provides a certificate of destruction? Does it dispose of toxic materials properly?

As an asset, customer data may be up for sale in the case of bankruptcy. However, all parties to a bankruptcy should be familiar with the Federal Trade Commission's lawsuit brought against ToySmart under Section 5 of the Federal Trade Commission Act ("FTC Act"), 15 U.S.C. § 45(a), for disclosing, selling or offering for sale personal customer information, contrary to the terms of the company's privacy policy that personal information would never be disclosed to third parties.

When disposing of waste and recycling paper, are all documents that contain personally identifiable information placed in secure padlocked containers or shredded?

(Shredding should be cross-cut, diamond-cut, or confetti-cut shredding, not simply continuous [single-strip] shredding, which can be reconstructed.) Does your recycling company certify its disposal/destruction methods? Is it bonded?

When engaging an external business to destroy records or electronic media, do you check references? Do you insist on a signed contract spelling out the terms of the relationship? Do you visit the destruction site and require that a certificate of destruction be issued upon completion?

When dealing with another company or government agency, do you ask about its security protocol regarding personal information? Do you inquire whether it shares that information with anyone? Do you find out if it does background checks on employees with access to your personal information. Contracts with outside service providers as well as employee agreements should specify that customer data is the company's exclusive property and should only be used as necessary to carry out contractor or employment duties. Such contracts and agreements should also incorporate the company's privacy and data security policies. Contracts should also delineate the service provider's specific obligations, rather than simply stating that the contractor will comply with all applicable laws.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Is the fax machine in a supervised area, off-limits to unauthorized persons? Is use restricted to authorized personnel only?

Is the fax machine used exclusively for sending non-confidential materials?

When sending documents, do all users complete a cover sheet that indicates the sender's and receiver's names, addresses and telephone numbers?

When confidential materials are sent, is notice of their confidential nature indicated on the cover sheet?

Do users always check the receiver's telephone number before transmitting documents? Do they compare the number displayed with number being called to check for errors? Do they check the transmission report after the fax has been sent?

When transmitting confidential materials, is the recipient notified in advance that the document is being sent? Does the sender check with the receiver to make sure the document has been received?

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

These machines are capable of storing an image of every document that has been copied, scanned, printed, emailed, or faxed. Although it may be stored in a proprietary language or encrypted, a hacker can easily gain access to years of sensitive data. Some machines don't even require hacking because they may allow jobs to be reprinted from a printed job list. Sophisticated copiers may contain a list of user's email addresses, outgoing fax numbers, and contact names. All of this information can easily be transferred from the copier to a hacker's laptop. Accordingly, simply disposing of this equipment presents a significant opportunity for a security breach.

While much of the hard drive space in many machines is used for processing, the drive may also store thousands of pages of information. Once the hard drive memory has been exceeded, files are automatically overwritten. "Cap points" limit the number of pages stored to hard drives, and the cap limitation will vary in each make and model. Depending on the type of machine, information from small print jobs may be stored in random access memory (RAM) only, and the files may be overwritten with each new print request, or lost when the machine is powered off.

Most major manufacturers now offer security or encryption packages to help protect against this problem. However, many businesses fail to pay for this protection. If your equipment does not have this protection, you should erase or remove the copier's hard drive, clear its memory, and change the copier's passcodes.

Does your organization have security procedures in place for deleting digital data from copiers, printers and fax/multifunction machines?

Does your organization recycle or resell copiers, printers or fax/multifunction machines to wholesalers or refurbishers? If so, does your organization take steps been taken to remove any data history?

CHAPTER 45: DETECTION OF CONFLICTS IN SECURITY POLICIES

Review Questions/Exercises

True/False

1. True
2. True
3. False
4. False
5. True

Multiple Choice

1. D
2. A
3. D
4. C
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Technical feasibility refers only to engineering possibility and is expected to be a "can/cannot" determination in every circumstance. It is also intended to be determined in light of the equipment and facilities already owned by a responsible entity. The responsible entity is not required to replace any equipment in order to achieve compliance with the cyber security standards. When existing equipment is replaced, however, the responsible entity is expected to use reasonable business judgment to evaluate the need to upgrade the equipment, so that the new equipment can perform a particular specified technical function in order to meet the requirements of these standards.

Although some standards do not require documentation and compensating measures when a determination of technical infeasibility has been made, responsible entities are free to do so in every such circumstance. Some standards do require such documentation and compensating measures because of the criticality of the specific requirement.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The phrase "reasonable business judgment" has an almost 200-year history in the business and corporation laws of America, Canada, and other Common Law nations. The phrase is meant to inform (any regulatory body or ultimate judicial arbiter of disputes regarding interpretation of these Standards) responsible entities that they have a significant degree of flexibility in implementing cyber security policy standards. Courts generally hold that the phrase indicates reviewing tribunals should not substitute their own judgment for that of the entity under review other than in extreme circumstances. A common formulation indicates that the business judgment of an entity (even if incorrect in hindsight) should not be overturned as long as it was made (1) in good faith (not an abuse or indiscretion), (2) without improper favor or bias, (3) using reasonably complete (if imperfect) information as available at the time of the decision, and (4) based on a rational belief that the decision is in the entity's business interest. This principle, however, does not protect an entity from simply failing to make a decision.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

As used in these cyber security policy standards, these five terms are intended to be understood generally as follows (although these informal definitions do indicate some degree of overlap, depending upon the context in which the terms are used):

1. DATA: information in a "raw" form; facts which may be represented or symbolized in records.
2. RECORDS: Records typically provide evidence of data, such as a "snapshot" in time of actions and events. A record may be in paper or "electronic" format (either analog or digital, such as "on" videotape or DVD, or "on" or "in" a hard-drive). Typically, official records (such as "business records") can only be modified or revised in compliance with proper and auditable trails, and thus can serve as objective, reliable evidence to demonstrate that a fact, situation or activity has occurred (thereby being usable, for instance, to demonstrate compliance with a requirement of these cyber security policy standards).
3. LOGS: Generally, a log is a specific type or collection of recorded data (generally, as pertaining to a series of similar or related actions or events) that may be generated automatically or manually. At a minimum, logs identify the event, who or what caused the event, and when the event occurred (a "time-stamp"). A log, as a type of record, can be in paper or electronic format. A log may also, in some contexts, be referred to as a type of document, and several similar (or a "set" of) logs may be referred to as a type of documentation.
4. DOCUMENTS: A document is a record that generally is used to represent or demonstrate what an organization has done or expects to do (such as a "business record" in the legal sense). Documents may include but are not limited to policies, processes and procedures, specifications, drawings, maps, etc. As a type of record, a document can be in paper or electronic format.
5. DOCUMENTATION: A series or collection of related documents generally pertaining to a particular issue. Documentation can be records that demonstrate what

an organization does, should do, or plans to do, including instructions to employees on how they should perform certain tasks. Documentation may also be records that represent, or can be used to demonstrate, what an organization has done or expects to do (such as a set of "business records"). Thus, the term "documentation" may be used to refer to any collection of documents (or "documentary" material) such as "business records," a plan or set of plans, a policy with associated procedures, or "the log" or "all the logs" generated by a specific system or device over a specified period.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

- Basic "port scans" to identify open/available services.
- File integrity checking to identify change in size of certain files.
- Review of active user accounts subsequent to changes to the system.
- Validate security-related functions: access controls, audit functions, file protection.
- Test for malicious logic in source code.
- Review technical documentation to determine security features.
- Review source code if available for application security.

CHAPTER 46: SUPPORTING USER PRIVACY PREFERENCES IN DIGITAL INTERACTIONS

Review Questions/Exercises

True/False

1. True
2. False
3. True
4. True
5. True

Multiple Choice

1. C
2. D
3. C
4. B
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

No. An organization is free to filter out requests before or after **a distributed access control system** is invoked on a web service request.

A distributed access control system can control access to a program that has its own authentication or authorization methods, because **the distributed access control system** does its work before the program runs. For example, the **distributed access control system** can be used to filter requests to a database application. The application does not need to be changed in any way and is unaware that the **distributed access control system** is even being used. Requests that are denied by a **distributed access control system** never reach the application, because the application is not executed. Requests that are granted by a **distributed access control system** allow the application to run and it may perform its usual authentication or authorization procedures.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Organizations will typically (but are not required to) trust each other's authentication services. Each organization is completely autonomous with respect to granting and denying access to its own information resources.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

To be authenticated by a **distributed access control system** at a particular organization, a user must already be known to that organization; that is, the organization must have previously established some way of confirming the user's identity, such as by providing the user with a username, secret password, and the name of the organization.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

No. And unless their organization requires it, users do not have to have client certificates.

If an organization chooses to authenticate a user using an X.509 certificate, it must merely be able to validate a client certificate passed to it by a **distributed access control system** and map the certificate to a **distributed access control system** username. In cases where the web server is configured to do this validation itself, a **distributed access control system** may not need to repeat this validation. If the organization is already using this certificate to authenticate its owner for other purposes (web access), it must also already have the necessary means of validating the certificate.

A **distributed access control system** obtains the X.509 certificate through its SSL connection with the user. It is possible to use self-signed certificates if an organization (or the federation) chooses to operate its own certificate authority. And, unless their organization requires it, users do not have to have client certificates. It is possible to use self-signed certificates if an organization chooses to operate its own certificate authority.

CHAPTER 47: PHYSICAL SECURITY ESSENTIALS

Review Questions/Exercises

3. True
4. False
5. True

Multiple Choice

1. C
2. D
3. C
4. C
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The data gathered by the stationary monitors and the deployable monitors are different. The stationary monitors send beta gross count rate and gamma gross count rate ranges. The beta gross count rate measures the radiation from all radionuclides that emit beta particles, which is indicated by the term gross or total. The term count rate tells us how quickly beta particles are being detected, which indicates how much radioactivity the monitor is seeing.

The gamma data measures radiation from all radionuclides that emit gamma raysand splits them into ranges of energy. The word gross, or total, indicates that the measurement is from all gamma emitting radionuclides. Not all gamma rays have the same amount of energy. Breaking the data into discrete energy ranges helps scientists to determine which radionuclides may be present.

The deployable monitors show external exposure rate. A graph would show the external exposure rate data, which is the dose, or amount of radiation, you would receive on the outside of your body if you were standing in that particular location. Background, or normal, radiation levels depend on factors including altitude and the amount of naturally occurring radioactive elements in the soil. Background external exposure rates typically range between 0.005 and 0.020 millirem per hour (mR/hr).

Both sets of data provide us with information on the type and amount of radioactive material in the air, and both serve the same purpose: to notify scientists, in near real time, of elevated levels of radiation so they can determine whether protective action is required. Following the Japanese nuclear incident, all of our near real time data showed background radiation levels.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

EPA's nationwide radiation monitoring system, RadNet, continuously monitors the nation's air and regularly monitors drinking water, milk and precipitation for environmental radiation. The network contains more than 100 air monitors across the United States and 40 deployable air monitors that can be sent to take readings anywhere in the country.

The near-real-time air monitoring data is continually reviewed by computer, and if the results show a significant increase in radiation levels, EPA laboratory staff is alerted immediately and further reviews the data to ensure accuracy. The system has been used to track radioactive material associated with foreign atmospheric nuclear weapons testing as well as for monitoring foreign nuclear accidents such as Chernobyl. EPA maintains additional monitoring capabilities that can be deployed to any location in the United States or its territories.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

During the last five years, EPA has been upgrading the nationwide RadNet system by installing new near-real-time radiation air monitors across the country. Currently the RadNet system contains more than 100 real-time radiation air monitors in 48 states. EPA also has 40 deployable monitors that can be sent to supplement the system.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

EPA has 40 deployable radiation air monitors that can be sent anywhere in the United States to gather data. The RadNet deployable monitors have built in weather stations and measure gamma radiation. Like all RadNet radiation air monitors, the RadNet deployable monitors send both weather and gamma radiation readings hourly to EPA's National Air and Radiation Environmental Laboratory.

CHAPTER 48: VIRTUAL PRIVATE NETWORKS

Review Questions/Exercises

True/False

1. False
2. True
3. False
4. False
5. False

Multiple Choice

1. C
2. C
3. B
4. A, E
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The organization first identified its needs based on its current operations and its stated future goals for secure remote access. In designing the proposed solution, the organization followed the typical steps of creating both an access control and an endpoint security policy: laying out its methods for authentication of users; designing an overall architecture for the expected remote access solution; selecting the hardware needed to meet its goals; specifying where in its current network the hardware will go; determining whether or not it needs a high availability solution; creating a management policy for the system and users; selecting the client software; designing the portal that the users will see when they connect to the system; and, developing an encryption policy.

After this design was completed, the organization implemented a prototype of the system before deploying it fully. The test plan for this prototype involved creating a sample configuration for the network access, the list of users for the system, definitions of the types of access that will be given to the users, and a specific policy plan linking the users to the types of access; as well as, other policy restrictions on the users.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The company calculated the network capacity required and determined the most cost effective access technologies for each site. They then quickly set up the IP VPN to connect five main sites with different bandwidth allocations, according to the specific requirements of each office. To solve its data center relocation dilemma, the company decided to take advantage of a co-location service and outsource the hosting of its core application and data servers. It leased more than adequate capacity for the company's data center with room to expand in the future.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

The company subscribed to a Virtual Private Network (VPN) service to meet all its telecommunications requirements. Its main offices are permanently linked via Multi-Protocol Label Switching (MPLS) technology with a capacity of 100 Mbps. Other remote sites are connected to this central VPN at any one time by using Asymmetric Digital Subscriber Line (ADSL) technology.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

The company initially developed the solution to securely connect its users spread throughout its global network of offices and data centers. The company anticipates this solution will save billions of dollars over dedicated point-to-point data circuits. This will provide comprehensive network security, reduced bandwidth costs, better user responsiveness and the ability for local offices to easily publish content for access by customers. In addition, the company supplied remote access for multiple service types (e-mail, file and print sharing, internet/intranet access, antivirus, remote support options, security, etc. . . .) to the staff across the world with minimal capital outlay with the shortest lead time; provided a secure transport method for internal information transfer; and, designed a transportable/scaleable/reproducible methodology that can be implemented in new offices with minimum capital cost and shortened time frames.

CHAPTER 49: IDENTITY THEFT

Review Questions/Exercises

True/False

1. True
2. True
3. False
4. True
5. True

Multiple Choice

1. C
2. E
3. D
4. D
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

- Requires you to supply personal information.
- Threatens to close or suspend your account if you do not take immediate action and provide personal information.
- Solicits your participation in a survey where you are asked to enter personal information.
- States that your account has been compromised or that there has been third-party activity on your account and requests you to enter or confirm your account information.
- States that there are unauthorized charges on your account and requests your account information.
- Asks you to enter your User ID, password or account numbers, PIN numbers or card expiration dates into an e-mail, non-secure webpage or text message.
- Asks you to confirm, verify, or refresh your account, credit card, or billing information.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

You can enhance security and help control risks when using your PC in a number of ways. Tips concerning PC access controls, virus management and software upgrades and maintenance follows:

Online Security Guidance PC Security

- Control physical access to your personal computer (PC); that is, do what you can to prevent unauthorized persons from using your PC.
- If you are using your PC and need to walk away from it for any reason, log off or lock your workstation.
- Select passwords that would be difficult for others to guess and change them frequently.
- Do not give your passwords to anyone. Do not save passwords on your website or leave written notes with your password near your PC
- Report suspicious activity you notice relating to your PC or use of your PC to the appropriate parties and do so as quickly as possible. If you notice suspicious activity relating to accounts at your bank that you access online, promptly report that activity to your bank account officer.

Virus Management

- Install virus management software on your PC and use it regularly.
- Keep it up to date (latest signature files, product upgrades).
- Be cautious when downloading and running programs or Java or ActiveX applets as they may contain unsecure data which cannot be filtered, for example, using firewall or anti-virus software.
- Use extreme caution when opening Email received from unknown sources and pay special attention to any attachments. Do not launch or open an attachment from an unknown source. When in doubt . . . delete it without opening it.

If you suspect your computer has a virus, here are some tips you may want to consider:

1. Make sure your anti-virus software has the most recent updates. If you aren't sure, please contact the software maker.
2. Run a complete scan using your updated anti-virus software.
3. Remove any dangerous or harmful files from your PC.
4. Change your e-mail password.
5. Contact your bank so that they can walk you through changing your User ID and Password.
6. Contact any other financial companies that you do business with online.

PC Software

- Understand and use the security features provided by your PC software, such as those included in many operating systems, browsers and word processing systems.
- Ensure that your browser uses the strongest encryption available and be aware of the level of encryption used when you connect to various sites and applications. Use only software from reliable vendors.
- Stay abreast of the latest release and patch levels of the PC software you use.

Encryption/Browser Check

Encryption is the scrambling of data into a code that is unreadable to anyone who does not have the key that deciphers it. Only you and your bank have the key to unlock your code. All your account information should be protected by at least 128-bit encryption to maintain the privacy and confidentiality of your data. To take advantage of strong encryption technology, you will need to obtain a secure browser, one that supports 128-bit encryption.

E-mail Tips

Do not provide your e-mail address to third party websites without reading the privacy and security policies and terms and conditions of these sites to ensure you understand the circumstances in which your e-mail address will be used.

If you suspect suspicious or fraudulent activity related to your bank account(s), please let us know right away. You should also contact your Internet Service Provider so they may block suspect companies from your e-mail inbox. To learn more about how to control and manage your incoming e-mails, please refer to your Internet Service Provider's online resources.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Identity theft and related account fraud happen when someone steals personal information such as your bank account number or Social Security number and poses as you, withdrawing money from your account and/or running up debt in your name.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

If you are a victim of Identity Theft or account fraud, you should call your bank customer service representative immediately. They will work with you to correct all unauthorized transactions in your bank accounts, and correct any inaccurate Credit Bureau reports. They will also provide you with additional information and direct you to other sources of assistance.

2. False
3. True
4. True
5. False

Multiple Choice

1. D
2. D

3. C
4. A
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

a. Startup cost – Although VOIP can be expected to save money in the long run, the initial installation can be complex and expensive. In addition, a single standard has not yet emerged for many aspects of VOIP, so an organization must plan to support more than one standard, or expect to make relatively frequent changes as the VOIP field develops.

b. Security – The flexibility of VOIP comes at a price: added complexity in securing voice and data. Because VOIP systems are connected to the data network, and share many of the same hardware and software components, there are more ways for intruders to attack a VOIP system than a conventional voice telephone system or PBX.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

No, except possibly for home use. VOIP demands high performance because voice communications must be in real time. A few seconds delay in data transmission is accepted and common, but a similar delay in a telephone conversation would make the system unacceptable to users. VOIP network equipment uses special protocols to over come the performance problems involved in transmitting voice over the Internet. Existing local area network cabling can be used.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

The term softphone refers to a telephone capability implemented on an ordinary PC, using only special software and a microphone/headset that plugs into the PC's audio ports. As noted in the body of this publication, though, softphones should not be used where security or privacy are a concern because of the ease with which they can be attacked. These systems are also more vulnerable to denial of service attacks from worms and viruses.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:
If all components have an uninterruptible power supply, the system should continue to function as long as the UPS batteries last. However, if the VOIP system is implemented on a cable modem, phone service will not be available during a cable outage. Similarly, if DSL is used, an outage of the DSL line will interrupt phone service. A conventional phone connection or mobile phones can serve as a backup.

CHAPTER 51: SAN SECURITY

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

SAN zoning is a method of arranging Fibre Channel devices into logical groups over the physical configuration of the fabric. SAN zoning may be utilized to implement compartmentalization of data for security purposes. Each device in a SAN may be placed into multiple zones.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

1. Snooping: Mallory reads data Alice sent to Bob in private Allows access to data
2. Spoofing: Mallory fools Alice into thinking that he is Bob Allows access to or destruction of data
3. Denial of Service: Mallory crashes or floods Bob or Alice Reduces availability.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

- Node Name/Port Name spoofing at Port Login time
- Source Port ID spoofing on dataless FCP commands
- Snooping and spoofing on FC-AL
- Snooping and Spoofing after Fabric reconfiguration
- Denial of Service attacks can be made in User mode

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

- Fibre Channel - Security Protocol (FC-SP) is a security protocol for Fibre Channel Protocol (FCP) and fiber connectivity (Ficon).
- FC-SP is a project of the Technical Committee T11 of the InterNational Committee for Information Technology Standards (INCITS) [http://www.t11.org/t11/stat.nsf/7db1e1431d9d045f852566dc004cc14d/43b527df16f4b28d85256b9a00653843?OpenDocument].
- FC-SP is a security framework which includes protocols to enhance Fibre Channel security in several areas, including authentication of Fibre Channel devices, cryptographically secure key exchange, and cryptographically secure communication between Fibre Channel devices.
- FC-SP is focused on protecting data in transit throughout the Fibre Channel network. FC-SP does not address the security of data which is stored on the Fibre Channel network.

CHAPTER 52: STORAGE AREA NETWORKING SECURITY DEVICES

Review Questions/Exercises

True/False

5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

When a computer interacts with a storage device, disk, tape, optical or RAID, this interaction occurs at the block level. Data is transferred in blocks rather than by the file. Block level transfer is considerably faster and easier to manage than file level transfer.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

A group of disk drives that collectively acts as a single storage system. Two types of storage arrays are available: RAID (Redundant Array of Independent Disks) and JBOD (Just a Bunch Of Disks). A RAID system provides fault tolerance by storing the same data redundantly on multiple disks, but appears as a single disk. A JBOD is, typically, a group of individual disks cabled together in a chassis with redundant power.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

A SAN solution should be used for applications that require large amounts of storage capacity and need block level access to the storage infrastructure. Additionally if you are looking to deploy a clustering solution such as Microsoft's Clustering technology a SAN must be used. Examples of SAN solutions include the Microsoft Exchange System and Oracle Databases.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

No, as long as the server is within the accepted standards and ratings for Fibre Channel over fiber optic cable. These distances are 175 meters (574.1 feet) over Multimode 62.5 micron cable, 500 meters (1640 feet) over a multimode 50 micron cable and 10 kilometers (6.214 miles) over 9 micron single mode cable.

CHAPTER 53: RISK MANAGEMENT

Review Questions/Exercises

1. False
2. True
3. True
4. True
5. True

Multiple Choice

1. B
2. B
3. D
4. A
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Continuous monitoring is one of six steps in the Risk Management Framework (RMF). The objective of a continuous monitoring program is to determine if the complete set of planned, required, and deployed security controls within an information system or inherited by the system continue to be effective over time in light of the inevitable changes that occur. Continuous monitoring is an important activity in assessing the security impacts on an information system resulting from planned and unplanned changes to the hardware, software, firmware, or environment of operation (including threat space). An organization's riskbased decisions (security authorization decisions) should consider how continuous monitoring will be implemented organization-wide as one of the components of the security life cycle represented by the RMF.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

No. Security authorization, requires the explicit review and acceptance of risk by an authorizing official on an ongoing basis. These risk-based decisions are based on security control assessments and continuous monitoring activities. Continuous monitoring does *not* replace the security authorization requirement for information systems. Rather, continuous monitoring is implemented as part of a holistic, risk management and (defense-in-depth) information security strategy that is integrated into enterprise architectures and system development life cycles. The continuous monitoring program, developed and implemented by an organization as a component in the RMF security life cycle-based approach, becomes a consideration in the risk-based decisions (security authorization decisions) rendered by authorizing officials.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Continuous monitoring in and of itself, does not provide a comprehensive, enterprise-wide risk management approach. Rather, it is a key component in the risk management process. The fundamental tenet of the unified information security framework is an enterprisewide risk management approach to information security that is life cycle-based and implemented across three hierarchical tiers within an organization (governance, mission/business process, and information system). The RMF, employs a security life cycle approach when considering information system security. The six-step RMF fundamentally transformed the previous certification and accreditation (C&A) process to provide emphasis on "front-end" and "back-end" security. The ongoing determination and acceptance of information system security-related risks remains the primary responsibility of authorizing officials and for which they are held accountable. Continuous monitoring activities contribute to helping authorizing officials make

better risk-based decisions, but do not replace the security authorization process.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Front-end security, exemplified by the first three steps in the RMF (security categorization, security control selection, and implementation), focuses on building security into information technology products and systems early in the system development life cycle. The initial steps are also linked to the organization's enterprise architecture and information security architecture. Better front-end security results in fewer weaknesses and deficiencies in information systems, directly translating to a lesser number of vulnerabilities that can be exploited by threat sources. Back-end security, exemplified by the last three steps in the RMF (security control assessment, information system authorization, and continuous monitoring), focuses on the effectiveness of the implemented security controls, the determination and acceptance of risk, and the ongoing monitoring of the security state of the information system. The RMF overall provides a disciplined and structured process that integrates information security and risk management activities into the system development life cycle.

CHAPTER 54: PHYSICAL SECURITY ESSENTIALS

Review Questions/Exercises

True/False

1. False

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

The company focused on identifying vulnerabilities in existing pedestrian and vehicle access controls and the overall security posture of the center. The company also provided specific security measure recommendations, priorities and cost-benefits, determined an action plan, including milestones, and provided a detailed description of the benefits and risks of the various approaches.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Structured interviews should be conducted with security managers, internal customers and other corporate functions to provide an overall perspective and identify issues for an external benchmark study. The study should be designed to identify similarities and differences between the physical security solution and its industry peers; as well as, other companies renowned to have superior physical security practices. This should provide a framework for choosing between alternatives for physical security investment and resourcing strategies. A detailed questionnaire should focus on the key topics identified. The data generated should identify potential areas for improvement and provide a baseline to document relative positioning within its industry.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

If the virtual fences are breached, or if specific behaviors are identified, visual and audible alarms are triggered. Additionally, a full range of intrusion detection sensors for facilities and barriers are available to enhance the intrusion detection system and protect high security facilities; these options include seizure vaults, safes, and other secure storage sites.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

The company developed a remote port entry system (a sub-system of the access control system, or ACS) that provides off-hours remote secure identification and US access to people and vehicles through select land ports of entry (LPOEs). The system uses video surveillance for visual identification of people and/or vehicles and integrates proximity-based ID cards, biometric identification and verification, radio frequency identification (RFID), voice-over internet protocol (VoIP), and remotely operated gates under the control of a command center (information and date are transmitted over a secure WAN). RFID tags are used on vehicles to ensure the identification of both people and their assigned vehicles. The company also uses a wide range of current and proven ACS technologies to control access of personnel, vehicles, and equipment through manned and unmanned perimeter check points, facilities, and secure areas.

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Organizations require a suite of plans to prepare themselves for response, continuity, recovery, and resumption of mission/business processes and information systems in the event of a disruption. Each plan has a specific purpose and scope; however, because of the lack of standard definitions for these types of plans, in some cases, the scope of actual plans developed by organizations may vary from the following basic descriptions.

A **COOP** is required by Homeland Security Presidential Directive (HSPD) - 20/National Security Presidential Directive (NSPD) - 51, *National Continuity Policy* and Federal Continuity Directive (FCD) - 1, *Federal Executive Branch National Continuity Program and Requirements* for sustaining an organization's (usually a headquarters element) *mission essential functions* (MEF) at an alternate site and performing those functions for up to 30 days before returning to normal operations. A **BCP** addresses sustaining mission/business processes and the information systems that support those mission/business processes during and after a significant disruption. BCPs are often developed at the organization's field level or for mission/business processes that are not prioritized as mission essential. A **CIP** plan is a set of policies and procedures that serve to protect and recover those components of the national infrastructure that are deemed so vital that their loss would have a debilitating effect of the safety, security, economy, and/or health of the United States. A **DRP** refers to an information system-focused plan designed to restore operability of one or more information systems at an alternate site after a major disruption usually causing physical damage to the original data center. An **ISCP** provides recovery and resumption procedures for a single information system resulting from disruptions that do not necessarily require relocation to an alternate site. A **Cyber Incident Response Plan** establishes procedures to enable security personnel to identify, mitigate, and recover from cyber attacks against an organization's information system(s). An **OEP** provides directions for facility occupants to follow in the event of an emergency situation that threatens the health and safety of personnel, the environment, or property.

Careful coordination must be maintained between plan developers to ensure that their respective policies and procedures complement one another. Any changes in one plan, system, or process must be communicated to plan developers of associated systems and functions.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The type of alternate site should be determined through the BIA with consideration of the FIPS 199 impact level. The alternate site choice must be cost-effective and match the availability needs of the organization's information systems. Thus, if a system requires near 100 percent availability, then a mirrored or hot site might be the right choice. However, if the system can

allow for several days of downtime, then a cold site might be a better option.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Notification procedures must be outlined in the ISCP. The ISCP Coordinator should determine who should be notified if a disruption occurs to the information system and in what sequence they should be contacted. Parties notified typically include the system owners, users, and interconnected information system points of contact. External entities that might be interconnected to the information system should also be included in the notification procedures. Design of a call tree will assist the sequence and responsibilities of executing notifications to appropriate contacts.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

In addition to integrating contingency planning into the SDLC, information system contingency planning should be coordinated with network security policies. System security controls can help to protect against malicious code or attacks that could compromise system availability and are closely coordinated with the incident response procedures. The ISCP should be closely coordinated with all other emergency preparedness plans related to the information system or interconnected systems and mission/business processes.

CHAPTER 56: BIOMETRICS

Review Questions/Exercises

True/False

1. True
2. False
3. False
4. False
5. False

Multiple Choice

1. C
2. D
3. A
4. A
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Biometrics are typically collected using a device called a sensor. These sensors are used to acquire the data needed for recognition and to convert the data to a digital form. The quality of the sensor used has a significant impact on the recognition results. Example "sensors" could be digital cameras (for face recognition) or a telephone (for voice recognition).

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

A biometric template is a digital representation of an individual's distinct characteristics, representing information extracted from a biometric sample. Biometric templates are what are actually compared in a biometric recognition system. Templates can vary between biometric modalities as well as vendors. Not all biometric devices are template based. For example, voice recognition is based on "models."

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

This depends on the specific modality being used. For example, with today's current technology, an individual would be required to touch a fingerprint sensor for the system to obtain the biometric sample, whereas face imaging for face recognition and iris imaging for iris recognition are contactless and would not require the user to touch the system.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Different applications and environments have different constraints. For instance, adequate fingerprint samples require user cooperation, whereas, a face image can be

captured by a surveillance camera. Furthermore, fingerprints are not available for many of the suspects on watch lists. There are also multiple biometric modalities for technical and financial reasons. Many scientists become interested in developing a system based on their own research. Upon a successful implementation, venture capitalist, interested in the implementation of such a system, commercialize a product. Therefore, wide varieties of modalities are being researched and are available on the market.

CHAPTER 57: HOMELAND SECURITY

Review Questions/Exercises

True/False

1. True
2. False
3. False
4. False
5. True

Multiple Choice

1. E
2. D
3. A
4. A
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

When there is credible information about a threat, an NTAS Alert will be shared with the American public. It may include specific information, if available, about the nature of the threat, including the geographic region, mode of transportation, or critical infrastructure potentially affected by the threat, as well as steps that individuals and communities can take to protect themselves and help prevent, mitigate or respond to the threat. The advisory will clearly indicate whether the threat is **Elevated**, if we have no specific information about the timing or location, or **Imminent**, if we believe the threat is impending or very soon.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The Secretary of Homeland Security will announce the alerts publically. Alerts will simultaneously be posted at DHS.gov/alerts and released to the news media for distribution. The Department of Homeland Security will also distribute alerts across its social media channels, including the Department's blog, Twitter stream, Facebook page, and RSS feed.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

The NTAS Alert informs the American public about credible terrorism threats, and encourages citizens to report suspicious activity. Where possible and applicable, NTAS Alerts will include steps that individuals and communities can take to protect themselves to help prevent, mitigate or respond to the threat. Individuals should review the information contained in the alert, and based upon the circumstances, take the recommended precautionary or preparedness measures for themselves and their families.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Citizens should report suspicious activity to their local law enforcement authorities. The "If You See Something, Say Something" campaign across the United States encourages all citizens to be vigilant for indicators of potential terrorist activity, and to follows NTAS Alert for information about threats in specific places or for individuals exhibiting certain types of suspicious activity.

CHAPTER 58: CYBER WAREFARE

Review Questions/Exercises

True/False

1. False
2. True
3. True
4. True
5. False

Multiple Choice

1. D
2. C

3. C
4. B
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

To address the advanced persistent cyber threat requires a multi-pronged effort by organizations. First, it requires a major change in strategic thinking to understand that this class of threat cannot always be kept outside of the defensive perimeter of an organization. Rather, this is a threat that in all likelihood, has achieved a foothold within the organization. This situation requires that organizations employ methods to constrain such threats in order to ensure the resiliency of organizational missions and business processes.

Second, it requires the development and deployment of security controls that are intended to address the new tactics, techniques and procedures (TTPs) employed by adversaries (supply chain attacks, attacks by insiders, attacks targeting critical personnel). Finally, to enable cyber preparedness against the advanced persistent cyber threat, organizations must enhance risk management and information security governance in several areas. These include, but are not limited to: (i) development of an organizational risk management and information security strategy; (ii) integration of information security requirements into the organization's core missions and business processes, enterprise architecture, and system development life cycle processes; (iii) allocation of management, operational, and technical security controls to organizational information systems and environments of operation based on an enterprise security architecture; (iv) implementation of a robust continuous monitoring program to understand the ongoing security state of organizational information systems; and (v) development of a strategy and capability for the organization to operate while under attack, conducting critical missions and operations, if necessary, in a degraded or limited mode.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

There are 3 basic parts to a cyber-attack:

1. *Access*: a method to get inside or gain access to a network or system
2. *Vulnerability*: some part of the system that the attacker can take advantage of or manipulate
3. *Payload*: the purpose of the attack, namely, what exactly is the target and how significant will the damage be

A safe cracker, for instance, must know where the safe is and how to get into it. The vulnerability would require knowledge of the safe, its locking mechanism and what aspects may be exploited. The payload, in this case, would be a bag full of money. Given these three aspects, prior intelligence is needed to understand what access is available and what vulnerability can be exploited in order to attack precise targets.

A standard computer virus, probably the most common form of a cyber-attack, may gain initial access to a computer or system in two ways: remotely or proximately. Some viruses, such as Conficker, spread through a network of computers (remote access) by exploiting holes in the network security or by attaching an infected USB drive to a computer. Such a virus is not only capable of ruining services on the computer itself, but also of blocking certain websites that might enable the user to eliminate the virus. A virus, Trojan, worm, etc. is primarily the means of carrying out a cyber-attack, while the real attack is the virus' payload.

There are many other forms cyber-attacks may take. A denial of service attack occurs when "an attacker attempts to prevent legitimate users from accessing information or services." This is typically accomplished when the attacker overloads a system with requests to view information. This would be an example of a remote attack. By extension, a distributed denial of service (DDoS) occurs when multiple computers are involved in a denial of service attack causing an even larger amount of traffic on the target website. This is the same concept as we've all experienced with cell phone disruption due to high usage.

Spearphishing is another simple method by which an attack may gain access to a computer system or network. Once some information about a target is acquired, an email is sent purporting to be from a legitimate company asking for information such as usernames and passwords to banking websites or network logins.

Backdoors, or hooks, are placed inside a computer or network in order to create a vulnerability that can be exploited later on. If direct access is possible, tampering with basic electronics is a simple type of cyber-attack. It is also possible that such software or even hardware could be installed into electronics by the original manufacturer. Some fear that this is what is being done in Chinese-produced microchips for various American computer companies.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

As cyber-attacks encompass a wide range of methods, they are also capable of affecting a very wide range of targets. Cyber-attacks can affect anything that is connected to a computer or a computer network. This would include not only single computers and network-connected computers but also USB storage devices and even machinery controlled by computer or network equipment. Due to the great diversity of possible targets for cyber-attacks, the next few sections will present several examples of cyber-attacks that have happened in the past. Despite fear over cyber-attacks on airline services or nuclear facilities, the most common and arguably the most dangerous are attacks on critical infrastructure.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

In the case of both cyber- and conventional espionage, plans can be discovered, strategies compromised and secrets stolen. During hostile attacks, systems can be shut down, communications cut off and infrastructure destroyed.

CHAPTER 59: SYSTEMS SECURITY

Review Questions/Exercises

True/False

1. True
2. True
3. False
4. False
5. True

Multiple Choice

1. D
2. A
3. D
4. C
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

A well-designed and well-managed continuous monitoring program can effectively transform an otherwise static and occasional security control assessment and risk determination process into a dynamic process that provides essential, near real-time security status-related information to senior leaders. Senior leaders can use this information to take appropriate risk mitigation actions and make cost-effective, risk-based decisions regarding the operation of their information systems. A continuous monitoring program allows an organization to track the security state of an information system on an ongoing basis and maintain the security authorization for the system over time. Understanding the security state of information systems is essential in highly dynamic environments of operation with changing threats, vulnerabilities, technologies, and missions/business processes.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Organizations are required to develop a continuous monitoring strategy for their information systems and environments in which those systems operate. A robust continuous monitoring program that derives from that strategy requires the active involvement of information system owners and common control providers, mission and business owners, chief information officers, senior information security officers, and authorizing officials.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Automation, including the use of automated support tools (vulnerability scanning tools, network scanning devices), can make the process of continuous monitoring more cost-effective, consistent, and efficient. Real-time monitoring of implemented technical controls using automated tools can provide an organization with a much more dynamic view of the security state of those selected controls. It is also important to recognize that with any comprehensive information security program, all implemented security controls, including management and operational controls, must be regularly assessed for

effectiveness, even if the monitoring of them is not easily automated. Sophisticated adversaries have been exploiting and continue to exploit the weakest controls, and true security for an information system or an organization is dependent on all controls remaining effective over time.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Organizations develop security plans containing the required security controls for their information systems and environments of operation based on mission and operational requirements. All security controls deployed within or inherited by organizational information systems are subject to continuous monitoring. This security control facilitates a defense-in-depth protection capability that includes people, processes, and technologies—a mutually reinforcing set of safeguards and countermeasures to address threats from cyber attacks, human error, and natural disasters.

CHAPTER 60: SECURING THE INFRASTRUCTURE

Review Questions/Exercises

2. False
3. True
4. False
5. False

Multiple Choice

1. C
2. D
3. C
4. B
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

It's appropriate to enable 802.1*x* authentication on any and all Ethernet ports on which you do not explicitly trust the device connected to the port. Be aware that to really trust the device, you need to have a high level of confidence in the physical security of the Ethernet switch, the device connecting to it, and the Ethernet cable path connecting them. It's generally assumed that wireless connections are not secure in real-world deployments. People widely recognize the need for security such as 802.1*x* on wireless links. Wired Ethernet does not enjoy the same widespread recognition of the need for extra security measures, so the requirements are explicitly identified here. Typically, the only places where you can be lax in deploying 802.1*x* are within data centers or wiring closets. For example, the connections from your servers, gateways, or other infrastructure devices such as routers and switches are not as susceptible to hackers unplugging the devices and trying to connect rogue devices. That being said, if you have a large organization in which numerous vendors come in and out of data centers with little accountability for who is doing what, you might consider deploying 802.1*x* even in these areas.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Although the common name for Ethernet port authentication is 802.1*x*, it might as well be called Extensible Authentication Protocol (EAP) for Ethernet ports. That's because the real authentication session is directly between the endpoints being authenticated and an access control server. This EAP exchange is carried over 802.1*x* Ethernet frames between the supplicant and the authenticating switch and over RADIUS between the switch and the authentication server.

As you might guess, EAP supports a variety of authentication mechanisms, and more methods can be added to this framework. The most common authentication choices include EAP-MD5 and EAP-TLS. The EAP-MD5 variant is similar to Challenge Handshake Authentication Protocol (CHAP), which traditionally has been used for dialup modem or ISDN remote access. This mechanism relies on a username/password combination for the authentication credentials. The EAP-TLS variant is more closely related to e-commerce applications, in which an X.509v3 certificate represents the server's identity and the client's identity is provided through another X.509v3 client-side certificate or username/password combination.

In addition to the authentication protocol in use, you need to understand whether a user of a device or a device itself is being authenticated. This distinction is important because user and device authentication solve different problems. For example, at a conceptual level, a multiaccess IP phone might have a single credential that proves to the network that it's not a rogue piece of hardware

touching the network. In this case, the individual user logins to the phone might trigger a user-based 802.1*x* authentication that lets a different set of QoS and security policies be applied to the switch port based on the individual user permissions.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Before you embark on a plan to configure 802.1*x* support on your Ethernet switches, you need to make sure that you coordinate with the desktop PC administrators so that they are ready to enable 802.1*x* in the client machines. As long as you need clients on your network that do not support 802.l*x*, you cannot widely implement 802.l*x*. You might be able to start a pilot project that applies to a limited set of Ethernet jacks in your campus, but note that these jacks do not permit clients lacking 802.1*x* support to connect. Don't forget to consider workgroup printers and other Ethernet devices along with desktop PCs.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Reaping the full security benefits of an 802.1*x* deployment involves important design considerations. Imagine that your network resources are a reservoir of water held back by a dam, and that dam is the security policy as implemented by access lists that filter traffic and authentication at the network's ingress points. Just as a dam must be watertight, all ports in an 802.1*x* deployment for ingress authentication must be part of the deployment. If you have any devices or users who cannot authenticate via 802.1*x*, or if you have Ethernet jacks with 802.1*x* not enabled, you have holes that need to be plugged. To gain access to the LAN segments that 802.1*x* is designed to protect, a hacker can simply use an Ethernet jack on which 802.1*x* is not enabled or masquerade as a user or device that does not support 802.1*x*.

Taking a more pragmatic approach, you can also prioritize the areas of physical access sensitivity. You should first roll out 802.1*x* support to the areas that are least regulated, such as lobbies and cafeterias with limited security checks. Next in order would be break rooms, temporary worker areas, or other areas with minimal restrictions. Finally, you can focus on the common office or cubicle areas. In general, work your way through from the least physically secure areas to the most physically secure.

CHAPTER 61: ACCESS CONTROLS

Review Questions/Exercises

True/False

2. False
3. True
4. False
5. False

Multiple Choice

1. D
2. D
3. C
4. C
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

There are four basic ways of authenticating users: asking for something only the authorized user knows (such as a password), test for the presence of something only the authorized user has (like a smart card), obtain some non-forgeable biological or behavioral measurement of the user (like a fingerprint) or determine that the user is located at a place where only the authorized user can enter. The best (and most effective) solutions require a combination of two or more authentication methods.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

The solution must be compatible with current operating systems and applications. Compatibility is a particularly big concern with biometric systems, since existing hardware and applications often must be adapted and/or reprogrammed to work with these tools.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Organizations must balance the value of the information being protected with the authentication and access control software's ease-of-use. Solutions that are difficult to use may protect systems, but only at the expense of user convenience and productivity.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

You'll want a product that you can use for many years. Over that time span, it will need to be upgraded to accommodate new security practices and technologies.

CHAPTER 62: ASSESSMENTS AND AUDITS

Multiple Choice

1. C
2. E
3. D
4. D
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

In the real world, the cost of protecting information must be balanced against the potential cost of security breaches. A company must fully understand the security risks it faces in order to determine the appropriate management action and to implement controls selected to protect against these risks.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Selecting the right set of controls requires the use of a risk assessment-based approach. This approach is a mandatory part of the PLAN (identify, analyze and evaluate the risks), DO (select, implement, and use controls to manage the risks to acceptable levels), CHECK, and ACT cyclic process defined in BS 7799-2 for the establishment, implementation, and maintenance of an ISMS.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

The standard specifies only that the organization should use a systematic approach to risk assessment (method of risk assessment, legal requirements, policy and objectives for reducing the risks to an acceptable level).

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

An organization that manages change effectively has a better chance of survival. The PDCA process model provides a means of assessing the risks an organization is challenged with as a result of changes in the business environment.

CHAPTER 63: FUNDAMENTALS OF CRYPTOGRAPHY

Multiple Choice

1. D
2. D

3. C
4. A
5. D

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

A cryptographic module is the set of hardware, software, and/or firmware that implements approved security functions (including cryptographic algorithms and key generation) and is contained within the cryptographic boundary. Another type, hybrid, is a software module that also contains an underlying unique hardware component. There are three distinct physical embodiments: single-chip modules, multiple-chip embedded modules, and multiple-chip standalone modules.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Cryptographic key management encompasses the entire lifecycle of the cryptographic keys used by a cryptographic module. This includes random number generation, key generation, key establishment (including key transport), key entry/output, key storage, and key zeroization. The requirements are applicable to modules that implement secret key and/or public key algorithms. Secret and private keys must be protected from unauthorized disclosure, modification and substitution. Public keys must be protected against unauthorized modification and substitution.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

The test types that must be performed are:

a. Power Up tests
b. Cryptographic algorithm test
c. Software/firmware Integrity test
d. Critical functions test
e. Conditional tests
f. Pairwise consistency test
g. Software/firmware load test
h. Manual key entry test
i. Continuous Random Number Generator test
j. Bypass test

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

A cryptographic module security policy consists of:

- A specification of the security rules, under which a cryptographic module shall operate, including the security rules derived from the requirements of the standard and the additional security rules imposed by the vendor.

The specification shall be sufficiently detailed to answer the following questions:

- What access does operator *X*, performing service *Y* while in role *Z*, have to security-relevant data item *W* for every role, service, and security-relevant data item contained in the cryptographic module?
- What physical security mechanisms are implemented to protect a cryptographic module and what actions are required to ensure that the physical security of a module is maintained?
- What security mechanisms are implemented in a cryptographic module to mitigate against attacks for which testable requirements are not defined in the standard?

When presenting information in the non-proprietary security policy regarding the cryptographic services that are included in the module validation, the security policy must include, at a minimum, the following information for each service:

- The service name
- A concise description of the service purpose and/or use (the service name alone may, in some instances, provide this information)
- A list of Approved security functions (algorithm(s), key management technique(s) or authentication technique) used by, or implemented through, the invocation of the service.
- A list of the cryptographic keys and/or CSPs associated with the service or with the Approved security function(s) it uses.
- For each operator role authorized to use the service:
  - Information describing the individual access rights to all keys and/or CSPs

- Information describing the method used to authenticate each role.

CHAPTER 64: SECURITY THROUGH DIVERSITY

Review Questions/Exercises

2. False
3. True
4. False
5. True

Multiple Choice

1. A
2. A
3. C
4. D
5. C

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Natural disasters cover only one threat vector to sustainability and operational readiness. The information age must balance uniformity and ubiquity in the face of threats though adaptation and vigilances.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

If you operate in a service industry that is Internet based, this question is perhaps what keeps you up at night—an attack against all your systems and services, from which you might not recover. Denial of Service (DoS) is a simple and straightforward attack that involves an attacker making enough requests to saturate your network or service to the point at which legitimate business and communications fails. The distributed denial-of-service (DDoS) attack is the same type of attack against a uniform presence in the Internet space but with many attacking hosts operating in unison against a site or service.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

It is possible but highly unlikely. Most browsers are not monolithic; adding code to view pages and perform animation are common practices. Browser extensibility allows anyone to integrate software components. Serious vulnerabilities and poor implementation in some of these extensions has led to exploitable code but usually demands a visit from a vulnerable browser. Since many of us don't use the same software package added to our browsers, this sort of threat, though risky to any enterprise from the standpoint of information disclosure, does not represent the sort of survivability issues security diversity seeks to remedy.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

It might not be possible to quantify the advantage of selecting diversity over ubiquity other than the cost in procurement, training, and interoperability. It is quite possible that an investment in "bucking the system" and using uncommon systems and services won't just cause issues; it would drive your competitive advantage into oblivion. This is the single biggest reason to avoid security through diversity, and it will be pointed out repeatedly. Security through diversity starts early and is embraced as a matter of survival. Military and financial institutions abide by the diversity principals in investments and decision-making. Though a threat is not always understood, the institutionalizing lessons learned tend to live on, forcing change and adaptation that require diversity as a fundamental principal of survival.

CHAPTER 65: ONLINE E-REPUTATION MANAGEMENT SERVICES

Review Questions/Exercises

True/False

1. False
2. False
3. True
4. False
5. False

Multiple Choice

1. A
2. A
3. B
4. C
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Absolutely not! You should never fall for this kind of fake promises, because there are a lot of fraudulent marketers. Online e-reputation management services is a complex area of online marketing; and, as you all know; just like traditional marketing, online e-reputation management services could never provide overnight effective solutions. The clients should understand that the major search engines are quite Daedalian structures and that it requires time, effort, great search engine optimization and communication skills. Expect your optimization results to improve gradually over time. Moreover, it takes time also to determine your stakeholders to participate, to be involved in the development of your Internet reputation and help shape it! No one is going to tell you that it will happen overnight; you can expect to see results in as little as 60 days. Depending on the complexity of the project, the duration is ranked between 3 months, 6 months or 1 year + .

The reasons why online e-reputation management services takes time: starting and running an Internet reputation campaign involves a lot of tasks. To begin with, online e-reputation management services will perform an Internet reputation audit in order to understand who the direct and indirect influencers of your reputation are. Research should be done to analyze one's personal or professional, business, industry or corporate reputation as represented by the content across various types of online media. The GAP analysis will help determine "Where are you?" and "Where do you want to be?" The reasons for any "reputation gap" will be assessed. Furthermore, an online reputation management specialist will establish and implement an online e-reputation management services plan and strategy. Finally, the online e-reputation management services success will be measured and delivered in form of reports to the client. One of the last steps of a successful online e-reputation management services process is the online reputation maintenance. You must keep your organic SEO natural to avoid penalties. All must happen gradually and not overnight. New websites, profiles etc don't rank immediately.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

You may be able to have the material removed, under particular legal circumstances, otherwise there is no guarantee and online e-reputation management services is dedicated to using only White-Hat-Techniques. Moreover, most of the online pages are archived at the Internet Archive. Furthermore, online e-reputation management services respects each constitution of each country, its privacy, the laws of the press and of the freedom of speech, so content that is protected by the law will not be removed. It is important to generate and promote new positive content.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Online e-reputation management services is capable of detecting and blocking web-based security risks, including phishing attacks. You have the option to configure the internal and external user policies.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Here are the levels that one can configure in a management console:

- High: Blocks URLs that are unrated, a Web threat, very likely to be a Web threat, or likely to be a Web threat.
- Medium: Blocks URLs that are unrated, a Web threat, or very likely to be a Web threat.
- Medium-Low: Blocks URLs that are a Web threat or very likely to be a Web threat.
- Low: Blocks only URLs that are a Web threat.

CHAPTER 66: CONTENT FILTERING

Review Questions/Exercises

True/False

1. False
2. True
3. False

4. True
5. False

Multiple Choice

1. B, E
2. B
3. D
4. A
5. E

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

- Content filtering can be implemented to prevent under age users from accessing inappropriate material on the Internet while allowing access to educational material.
- Content filtering can be used to prevent access to material that is illegal such as child pornography.
- Content filtering can be an effective means of limiting the liability that institutions face by providing Internet access.
- Content filtering can be used to increase employee productivity by restricting access to inappropriate or non-work related sites.
- Content filtering can conserve bandwidth, freeing existing bandwidth for mission-critical needs and decreasing the need to purchase additional bandwidth.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Content filtering will introduce a few milliseconds to the transaction time for each site accessed. This additional time will not be perceptible to users. Some institutions may actually experience faster download times in situations where a significant amount of inappropriate traffic is removed by content filtering.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

No, only constituents who subscribe to content filtering will have their Internet traffic directed to the content filtering equipment on the backbone. Other constituents will be completely unaffected.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

When a user attempts to access a blocked site, the software will redirect the user to a web page indicating that the content filter has blocked access to that site.

CHAPTER 67: DATA LOSS PROTECTION

5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

1. Ground-based threats;
2. Space-based threats;
3. Interference oriented threats.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Basic Interoperable Scrambling System, usually known as BISS, is a satellite signal scrambling system developed by the European Broadcasting Union and a consortium of hardware manufacturers. Prior to its development, "ad-hoc" or "Occasional Use" satellite news feeds were transmitted either using proprietary encryption methods (PowerVu), or without any encryption. Unencrypted satellite feeds allowed anyone with the correct equipment to view the program material.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

PowerVu is a conditional access system for digital television developed by Scientific Atlanta. It is used for professional broadcasting, notably by Retevision, Bloomberg Television, Discovery Channel, AFRTS and American Forces Network. PowerVu is also used by cable companies to prevent viewing by unauthorized viewers. PowerVu has decoders that decode signals from certain satellites for cable distribution services. These decoders can also be used just like the FTA (Free-To-Air) satellite receivers if properly configured. PowerVu was considered highly secure since it uses a complicated system to authorize each PowerVu receiver and trace its history of ownership and usage. Most PowerVu users are professional cable or satellite companies, using the service and equipment for signal redistribution, because regular users cannot afford it. On March 10, 2010, the hacker called "Colibri" published after previous work done in 2005 a cryptanalysis of a PowerVU system implementation, describing a flawed design that can be used to gain access to the encryption keys and ultimately decryption of the transmitted content.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

DigiCipher 2, or simply DCII, is a proprietary standard format of digital signal transmission and encryption with MPEG-2 signal video compression used on many communications satellite television and audio signals. The DCII standard was originally developed in 1997 by General Instrument, which is now the Home and Network Mobility division of Motorola. The original attempt for a North American digital signal. encryption and compression standard was DigiCipher 1, which was used most notably in the now-defunct PrimeStar medium-power direct broadcast satellite (DBS) system during the early 1990s. The DCII standard predates wide acceptance of DVB-based digital terrestrial television compression (although not cable or satellite DVB) and therefore, is incompatible with the DVB standard. The primary difference between DigiCipher 2 and DVB lies in how each standard handles SI, or System Information. DigiCipher 2 also relies on the fact that its signals must be understood in terms of a virtual channel number in addition to the DCII signal's downlink frequency, whereas DVB signals have no virtual channel number. Approximately 70% of newer first-generation digital cable networks in North America use the 4DTV/DigiCipher 2 format. The use of DCII is most prevalent in North American digital cable television set top boxes. DCII is also used on Motorola's 4DTV digital satellite television tuner and Shaw Direct's DBS receiver.

CHAPTER 69: VERIFIABLE VOTING SYSTEMS

Review Questions/Exercises

True/False

1. True
2. True
3. False
4. False
5. True

Multiple Choice

1. D
2. A
3. D
4. C
5. A

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Their difference is that in secret sharing, there needs to be a trusted authority to distribute the secret information among all the parties. But in threshold techniques, no trusted authority is needed, and all parties can work together to generate the secret information and distribute it among themselves. Here, we review some basic secret sharing techniques and the threshold ElGamal. Note that the threshold RSA and threshold Paillier are also feasible, but they are more complex.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

Zero-knowledge: There exists an expected polynomial-time algorithm which can produce, upon input of the assertion to be proven but without interacting with the real prover, transcripts indistinguishable from those resulting from interaction with the real prover.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

It can be used to prove that a party knows the solution of k out of n problems without revealing which problems she/he can solve. This protocol is normally used in verifiable voting schemes to prove that a ciphertext is an encryption of one value within a subset of different values.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

It takes a list of encrypted values as input, and outputs a list of values (encrypted or decrypted depending on the type of mixnet) corresponding to the input list, but permuted so the links between individual inputs and outputs are hidden. When the mixnet receives a number of encrypted values as inputs, each mix server will either partially decrypt (in a decryption mix) or re-encrypt (in a re-encryption mix) each of the encrypted values and output the results to the next mix server in a permuted order. Therefore, if there exists at least one honest mix server, the relationships between the mixnet inputs and outputs will be kept private. However, the main challenge is how to efficiently prove that the mixnet has generated the

correct outputs without revealing the inputs and outputs relationships.

CHAPTER 70: ADVANCED DATA ENCRYPTION

Review Questions/Exercises

True/False

1. True
2. False
3. False
4. False
5. True

Multiple Choice

1. E
2. D
3. A
4. A
5. B

Exercise

Solution

The following is a partial exercise solution. The students should be able to expand on the following:

Advanced data encryption is done either by computer programs or by specially designed computer hardware devices. These programs or devices apply a mathematical algorithm (a recipe for producing encrypted data) to the information. The output is a scrambled form of the original data. When a legitimate user needs to access the data, the scrambling process is reversed and the data is restored to its original form. Only those who are in possession of the "key" can unscramble ("decrypt") the data.

Hands-on Project

Solution

The following is a partial project solution. The students should be able to expand on the following:

A key is a piece of data that an advanced data encryption algorithm uses to determine exactly how to unscramble the protected information. It is called a key because it "unlocks" the encryption formula to unscramble the encrypted data.

Case Projects

Solution

The following is a partial project solution. Students should be able to expand on the project analysis through extensive research.

Actually, there are three types of keys: "secret," "public" and "private." Different advanced data encryption algorithms use different types of keys. The more traditional advanced data encryption algorithm schemes use secret keys to both encrypt and decrypt data. Newer methods of advanced data encryption algorithm, known as "public-key" algorithms, use a public key to encrypt a piece of information and its corresponding private key to decrypt the information.

Optional Team Case Project

Solution

The following is a partial solution to aid students in coming up with their own solution to solve this case:

Any kind of data can be encrypted. You can encrypt plaintext files. PDF documents, spreadsheets, images and any other form of information in your computer. You can even encrypt database information and information on back-up media.

Chapter 29

Firewalls

Dr. Errin W. Fulp
Wake Forest University

Note: This chapter is available in its entirety online at store.elsevier.com/product.jsp?isbn=9780123943972 (click the Resources tab at the bottom of the page). It is also available in print in *Managing Information Security*.

1. ABSTRACT

The purpose of the firewall and its location is to have network connections traverse the firewall, which can then stop any unauthorized packets. A simple firewall will filter packets based on IP addresses and ports. A useful analogy is filtering your postal mail based only on the information on the envelope. You typically accept any letter addressed to you and return any letter addressed to someone else. This act of filtering is essentially the same for firewalls. This chapter refers to the secure network as the internal network; the insecure network is the external network. The remainder of this chapter provides an overview of firewall policies, designs, features, and configurations. Of course, technology is always changing, and network firewalls are no exception. However, the intent of this chapter is to describe aspects of network firewalls that tend to endure over time.

2. CONTENTS

1. **Introduction**
2. **Network Firewalls**
3. **Firewall Security Policies**
   - Rule-Match Policies
4. **A Simple Mathematical Model for Policies, Rules, and Packets**
5. **First-Match Firewall Policy Anomalies**
6. **Policy Optimization**
   - Policy Reordering
   - Combining Rules
   - Default Accept or Deny?
7. **Firewall Types**
   - Packet Filter
   - Stateful Packet Firewalls
   - Application Layer Firewalls
   - Nation-State Backed
8. **Host and Network Firewalls**
9. **Software and Hardware Firewall Implementations**
10. **Choosing the Correct Firewall**
11. **Firewall Placement and Network Topology**
    - Demilitarized Zones
    - Perimeter Networks
    - Two-Router Configuration
    - Dual-Homed Host
    - Network Configuration Summary
12. **Firewall Installation and Configuration**
13. **Supporting Outgoing Services through Firewall Configuration**
    - Forms of State

Identity Theft

Markus Jakobsson
Palo Alto Research Center

Alex Tsow
The MITRE Corporation

Note: This chapter is available in its entirety online at store.elsevier.com/product.jsp?isbn=9780123943972 (click the Resources tab at the bottom of the page).

1. ABSTRACT

This chapter focuses on identity manipulation tactics in email and Web pages. It describes the effects of features ranging from URL plausibility to trust endorsement graphics on a population of 398 subjects. The experiment presents these trust indicators in a variety of stimuli, since reactions vary according to context. In addition to testing specific features, the test gauges the potential of a tactic that spoofs third-party contractors rather than a brand itself. The results show that indeed graphic design can change authenticity evaluations and that its impact varies with context. We expected that authenticity-inspiring design changes would have the opposite effect when paired with an unreasonable request, but our data suggest that narrative strength, rather than underlying legitimacy, limits the impact of graphic design on trust and that these authenticity-inspiring design features improve trust in both legitimate and illegitimate media. Thus, it is not what is said that matters but how it is said: An eloquently stated unreasonable request is more convincing than a poorly phrased but quite reasonable request.

2. CONTENTS

1. **Experimental Design**
   Authentic Payment Notification: Plain versus Fancy Layout
   Strong Phishing Message: Plain Versus Fancy Layout
   Authentic Promotion: Effect of Small Footers
   Weak Phishing Message
   Authentic Message
   Login Page
   Login Page: Strong and Weak Content Alignment
   Login Page: Authentic and Bogus (But Plausible) URLs
   Login Page: Hard and Soft Emphasis on Security
   Bad URL, with and without SSL and Endorsement Logo
   High-Profile Recall Notice
   Low-Profile Class-Action Lawsuit
2. **Results and Analysis**
3. **Implications for Crimeware**
   Example: Vulnerability of Web-Based Update Mechanisms
   Example: The Unsubscribe Spam Attack
   The Strong Narrative Attack
4. **Summary**
5. **Chapter Review Questions/Exercises**
   True/False
   Multiple Choice
   Exercise

Note: This chapter is available in its entirety online at store.elsevier.com/product.jsp?isbn=9780123943972 (click the Resources tab at the bottom of the page).

1. ABSTRACT

One thing to consider is that the most probable avenue of attack in a SAN is through the hosts connected to the SAN. There are potentially thousands of host, application, and operating system-specific security considerations that are beyond the scope of this chapter but should be followed as your systems and application administrators properly configure their owned devices. Information security, that aspect of security that seeks to protect data confidentiality, data integrity, and access to the data, is an established commercial sector with a wide variety of vendors marketing mature products and technologies, such as VPNs, firewalls, antivirus, and content management. Recently there has been a subtle development in security. Organizations are expanding their security perspectives to secure not only end-user data access and the perimeter of the organization but also the data within the datacenter. Several factors drive these recent developments. The continuing expansion of the network and the continued shrinking of the perimeter expose datacenter resources and the storage infrastructure to new vulnerabilities. Data aggregation increases the impact of a security breach. IP-based storage networking potentially exposes storage resources to traditional network vulnerabilities. Recently the delineation between a back-end datacenter and front-end network perimeter is less clear. Storage resources are potentially becoming exposed to unauthorized users inside and outside the enterprise. In addition, as the plethora of compliance regulations continues to expand and become more complicated, IT managers are faced with addressing the threat of security breaches from both within and outside the organization. Complex international regulations require a greater focus on protecting not only the network but the data itself. This chapter describes best practices for enhancing and applying security of SANs.

2. CONTENTS

1. **Organizational Structure**
   AAA
   Restricting Access to Storage
2. **Access Control Lists (ACL) and Policies**
   Data Integrity Field (DIF)
   Zoning and Isolating Resources
3. **Physical Access**
4. **Change Management**
5. **Password Policies**
6. **Defense in Depth**
7. **Vendor Security Review**
8. **Data Classification**
9. **Security Management**
   Security Setup
   Unused Capabilities
10. Auditing
   Updates
   Monitoring
   Security Maintenance
11. **Security Maintenance**
   Limit Tool Access
   Secure Management Interfaces
12. **Host Access: Partitioning**
